

QUANTITATIVE PROTEOMIC ANALYSIS OF THE HUMAN IMMUNE RESPONSE  
FOLLOWING INFLUENZA VACCINATION

By

Allison C. Galassie

Dissertation

Submitted to the Faculty of the  
Graduate School of Vanderbilt University  
in partial fulfillment of the requirements

for the degree of

DOCTOR OF PHILOSOPHY

in

Chemistry

May, 2017

Nashville, Tennessee

Approved:

Andrew J. Link, Ph.D.

C. Buddy Creech, M.D.

John A. McLean, Ph.D.

David W. Wright, Ph.D.

## ACKNOWLEDGMENTS

The work presented in this dissertation could not have been possible without the generous financial support of Vanderbilt University and the Immunobiology of Blood and Vascular Systems training program (IBVSTP) grant (5T32HL069765-12). The IBVSTP grant's Inflammation Forum gave me the opportunity to expand my knowledge into the field of immunology, a brand new field to me. The forum also gave me many opportunities to present my work to other members and get helpful feedback along the way. I really have the IBVSTP to thank for the confidence in my public speaking skills.

There have been a number of people who helped guide me through graduate school. First, I would like to thank my PhD advisor, Dr. Andrew Link for giving me the opportunity to train and work under his guidance. I came to his lab in the Department of Pathology, Microbiology, and Immunology with no significant knowledge in any of those subjects, yet he gave me the opportunity to expand my knowledge base and become a mixture of an immunological chemist and chemical immunologist. His advice and critiques have helped me grow as a person and confident scientist. I would especially like to thank him for providing me with the wonderful opportunities for me to learn and present my work at many conferences around the nation.

I would like to thank the members of my doctoral committee Drs. John McLean, David Wright, and Buddy Creech. While still stressful, committee meetings and exams were lightened by your presence and humor. I am very grateful for your advice on how to tell the analytical story of my research, the push to present for the chemistry forum, and the friendly conversations had along the way. I would also like to thank all of the collaborators who have made my life interesting over the past few years: Dr. Leigh Howard, Dr. Kathryn Edwards, Johannes Goll, Travis Jensen, Dr. Sebastian Joyce, Dr. James Thomas, Dr. Nripesh Prasad, Dr. Mark Boothby, and Dr. Tom Dever. Each project offered new challenges and interesting biology for me to learn.

Thank you to the Link Lab members, both former and current, for helping me on this journey. Dr. Parimal Samir took me under his wing during my rotation and taught me everything he knew about being the main operator of our mass spectrometers. Being very well read, he was the first one to tell me about newly published research and taught me the benefit of being well read outside of my focus. He also provided me a lot of help and advice regarding my projects and politely pointed out the flaws before someone else did. Dr. Kristen Hoek helped me immensely with understanding the biological aspects of my project, the cell work project that is still in its initial stages, and the editing of manuscripts. I would like to extend my thanks to the rest of the Link Lab members I've had the pleasure of working with: Drs. Chris Browne, Tara Allos, and Xinnan Niu.

On a personal note, I would like to thank Alexis Wong, Lauren Gibson, Brad Durbin, Bryson Howard, Chad Chumbley, and Jessica Moore for not only being colleagues but also friends. Alexis and Lauren – Thank you for bringing me up when I was down and celebrating with me when things were perfectly right. I could not have asked for better friends during the most trying years of my life. Now we just need to get going on those Nashville bucketlists! Brad and Bryson – Thank you for always being funny and making sure I was social every once in a while. Chad – Thank you for not assuming I was a stalker when I not only chose the same graduate school as you, but the same apartment complex as well. I am forever grateful for being able to call you over to kill giant spiders for me and for the board game fun on snow days. Jessica – Thank you for making me an honorary Caprioli lab member during ASMS conferences and making sure I was never kidnapped when returning to my hotel. Through you, I met a number of other Caprioli group members to talk to and I never felt awkward or unwelcome at all.

The decision to come to graduate school was not easy, but various people helped with the decision. I would like to thank my high school teachers and college professors for the support and guidance. Mr. Spigner – I can trace where I am today back to the pivotal moment in your 9<sup>th</sup> grade physical science class when I discovered that chemistry was my passion. Dr. Vance – Thank you for helping me realize that I will be even more valuable to the forensic science community with a

graduate degree. Dr. Darrin Smith – Thank you for allowing me to conduct undergraduate research with you. It was a difficult project, but gave me helpful insights into what real chemistry research is like. I look forward to bumping into you at future ASMS conferences. Dr. Lori Smith – Thank you for taking a chance on me as an intern and then allowing me to continue as a part-time technician. I have a much stronger stomach thanks to you and a horse placenta in a blender. The experience I gained at the UK VDL is unquantifiable. Thank you for your influence and continued friendship. Lindsay Huffman – Thank you for being my Colonel Camp buddy and first Eastern Kentucky friend. I cannot imagine what EKU would have been like without you. Thank you for being so supportive of what I'm doing and encouraging me. Ethan Kilgore – Most people thought we were crazy when we decided to try long distance while both being in PhD programs, however we have made it work and are better for it. While vastly different than what you study, you never once have minded helping me talk through an experiment issue or practice a presentation, even when you have other things to do. No one understands the ups and downs in my life quite like you do. Thank you for the support, encouragement, and companionship.

Finally, I would like to thank my family for their love and support. Adrienne – thanks for being a great sister and lamenting with me from time to time about the difficulties of graduate school. Mom and Dad – I would not have made it this far without you and your encouraging Winnie the Pooh and Willy Wonka quotes. You have supported every decision I made, even when it meant leaving home at 16 to go to the special math and science school. Thanks for raising me to be the person I am today. I am eternally grateful for everything you have done and provided for me. I love you.

# CHAPTER I

## INTRODUCTION

### Introduction to influenza

Influenza is one of the most well-known viruses and infectious diseases because of its global spread and seasonal patterns. Influenzas are enveloped viruses that contain 7-8 negative-sense, single-stranded RNA segments, which code for up to 14 different proteins (Figure 1.1). Based on immunologic and biologic properties, influenza viruses are divided into three main types: A, B, and C.<sup>1</sup> Influenza A, the major genera infecting humans, is further divided into subtypes and named based on the two major membrane glycoproteins: hemagglutinin (HA) and neuraminidase (NA). Eighteen HA and 11 NA subtypes have been identified thus far, however not all types cause human infection.<sup>2</sup>

**Figure 1.1 Influenza virus structure.**<sup>3</sup> Reprinted with permission from AAAS.

Each year 3-5 million infections and 250,000-500,000 deaths associated with seasonal influenza outbreaks occur worldwide.<sup>4</sup> While there is a seasonal influenza vaccine, it has to be updated each year to match the strains circulating in the population.<sup>5</sup> Influenza viruses have no RNA polymerase proofreading activity, which yields an error rate of approximately one mutation per replicated genome.<sup>6</sup> As mutations build up (antigenic drift), the virus can escape immune surveillance and require a new vaccine. Additionally, the segmented nature of the RNA genome allows for major antigenic changes through reassortment of co-infecting viruses, typically in an intermediate host (antigenic shift).<sup>7</sup> This introduces new HA and/or NA subtypes into a naïve human population, which can lead to pandemics (Figure 1.2).

**Figure 1.2 Timeline and evolution of pandemic influenza viruses.**<sup>8</sup> Pandemics in the 20<sup>th</sup> century were caused by various reassortments with between birds, pigs, and humans. The color of the proteins and gene segments represent the originating species: pink = avian, green = human, yellow = human, blue = swine, purple = swine. Future pandemic viruses could emerge from antigenic drift, antigenic shift, or re-emergence of old strains. Reprinted from Trends in Microbiology, with permission from Elsevier.

The 1918 Spanish Influenza (H1N1) pandemic infected 20-40% of the world's population and killed approximately 50 million people, making it the worst influenza pandemic on record.<sup>9</sup> Three other influenza pandemics occurred in the 20<sup>th</sup> century and one in the 21<sup>st</sup> century. Fortunately, these pandemics have not been as catastrophic. All five of these pandemic influenza viruses had

some form of avian origin.<sup>10-12</sup> Today, the biggest potential pandemics are highly pathogenic avian influenza (HPAI) viruses. The first direct HPAI transmission from birds to humans occurred in 1997 in Hong Kong with H5N1.<sup>13</sup> Since then, there have been 856 confirmed human cases and a 53% mortality rate (Figure 1.3).<sup>14</sup> Almost all of the cases have occurred from direct bird-to-human transmission. The failure of the viruses to be readily transmitted from human to human has kept it from becoming a pandemic.

Figure 1.3 Locations of confirmed human cases for avian influenza A (H5N1).<sup>14</sup>

H5N1 is a very diverse avian influenza subtype. The World Health Organization (WHO) has created a unified nomenclature system for the many clades and sub-clades of H5N1 that is

continuously updated when clades diverge (Figure 1.4).<sup>15-16</sup> Given how quickly H5N1 has diversified in ten years, it is reasonable to worry about if the mutations acquired over time will eventually lead to human-to-human transmissibility in the near future. In fact, Herfst *et al.* showed that only five mutations were necessary for H5N1 to become airborne and transmissible between ferrets, an accepted model for human transmissibility.<sup>17</sup>

**Figure 1.4. Evolution of the H5 hemagglutinin protein.** Over time, the WHO has divided the clades into second order, third order, etc. clades based on nucleotide divergence in the H5 HA protein.<sup>15</sup>

### Immune responses to infections and vaccines

The human immune system is a complex collection of different organs, cell types, and effector molecules, that recognize, neutralize, and eliminate infectious microorganisms, such as the

influenza virus.<sup>18</sup> This complex system also recognizes and responds identically to microbial antigens in vaccines to produce immunological protection against the naturally occurring pathogenic organisms. The immune system is divided into two branches: the innate and adaptive systems. Both branches are defined by specialized cell types and functions (Figure 1.5)

**Figure 1.5 Overview of the immune response timeline after a vaccine is given.** Cell icons reproduced from Janeway's Immunobiology by Murphy, Kenneth et al. with permission of Garland Sciences via Copyright Clearance Center.

The innate immune system acts as the first line of defense against infectious agents. It responds rapidly, but does not lead to long lasting, protective immunity against the pathogen. Innate cells, including neutrophils, macrophages, natural killer cells (NK), and dendritic cells (DC), rely on a limited number of receptors and secreted proteins to recognize and respond to common foreign antigenic features termed pathogen associated molecular patterns (PAMPs).<sup>18</sup> Microbial products including lipopolysaccharides, peptidoglycans, bacterial RNA and DNA, and lipoteichoic

acid are examples of PAMPs recognized by the host's innate pattern recognition receptors (PRRs). When pathogens are detected, they are phagocytized and degraded by the innate cells. The activated innate cells secrete numerous cytokines and chemokines that, in turn, activate and recruit other immune cells to the site of infection. NK cells, while innate in nature, are derived from the lymphoid lineage, while the other innate cell types differentiate from the myeloid lineage. A unique feature of NK cells is their ability to recognize stressed cells and directly induce apoptosis in cells that are missing key cell surface receptors.<sup>18</sup>

Macrophages and DCs, also called antigen-presenting cells, display peptides from the destroyed pathogen on their cell surface using the major histocompatibility complex (MHC) protein complex. The MHC is a group of cell surface proteins that controls a large portion of the immune system in all vertebrates. The MHC binds pathogen-derived peptide fragments and displays them on the host's cell surface for T cells to recognize.<sup>18</sup> In a healthy cell, the proteasome degrades intracellular proteins into short peptides and amino acids for recycling and building of new proteins. Some of these peptides are transported to the endoplasmic reticulum, where they are associated with MHC class I molecules and are presented on the cell's surface in the MHC complex, which indicates the cell is healthy.<sup>19</sup> MHC class II receptors display peptides derived from extracellular proteins that have been phagocytosed and digested in the lysosomes of the host cell. Antigen-presenting cells migrate to the lymph nodes where they present peptides in the context of MHC to naïve, antigen-specific T cells, thus activating them.<sup>18</sup>

Compared to the innate immune response, an adaptive immune response takes longer to generate, but is highly specific to the particular antigen and pathogen. Critically important, the adaptive immune system provides long-lasting protection against the pathogen, which is the ultimate goal of vaccination. There are two broad classes of adaptive responses. First, B lymphocytes are responsible for the humoral antibody response.<sup>18</sup> Each B cell has a unique B-cell receptor on its surface, which binds to one particular antigen. Naïve B cells whose receptors bind antigen and receive a secondary signal from a T-helper cell differentiate into either plasma

cells or memory B cells.<sup>18</sup> Plasma cells proliferate and secrete large amounts of antibodies that recognize the targeted pathogen, neutralize it, and mark it for destruction. Next, T lymphocytes are responsible for cell-mediated immunity, which recognizes and destroys infected host cells. Several subsets of T cells exist, each with a different function. T-helper cells assist other cells, such as B cells, macrophages, and cytotoxic T cells, in their functions. This type of T cell becomes activated from interaction with MHC class II complexes. Cytotoxic T cells destroy infected host cells by recognizing foreign antigens displayed in the context of the MHC class I receptor on the surface of the infected cell. Finally, regulatory T cells are critical for the maintenance of tolerance by shutting down cell-mediated immunity at the end of the infection. Long-lived memory B and T cells enable the immune system to rapidly respond to and neutralize secondary infections by pathogens that have previously been encountered (Figure 1.6).<sup>18</sup> The protective function of the memory adaptive immune response includes neutralizing the pathogens before they can enter host cells, as well as recognizing and destroying pathogen-infected cells before the pathogen can multiply. Vaccines mimic pathogenic infections by stimulating the immune system to respond and acquire immunological memory.

**Figure 1.6 The principle of vaccine induced immunological memory as illustrated with a tetanus toxoid vaccine.** Vaccination with a chemically modified tetanus toxin produces a toxoid, which has no toxicity, but retains its epitopes. A primary antibody response is formed against this toxoid. Later when a natural infection of tetanus toxin occurs, B cells are restimulated and produce a faster and more intense secondary antibody response to the original epitope. From Roitt et al. 2001.<sup>20</sup>

## **A brief history of influenza vaccines**

Vaccinating against the influenza virus is the primary approach for controlling the infection. As vaccines mimic natural pathogenic infections by stimulating the immune system to respond and acquire immunological memory, inactivated and live attenuated vaccines have been developed.<sup>21</sup> A live attenuated influenza vaccine (LAIV) was first developed in 1936,<sup>22-23</sup> followed by an inactivated influenza vaccine in the 1940s.<sup>24</sup> Live attenuated vaccines are passed through a foreign host to become less pathogenic, while inactivated vaccines use heat or formaldehyde to kill the pathogen.<sup>9</sup> Over time, whole-virus vaccines have been largely replaced with purified split virus and subunit vaccines in order to reduce reactogenicity. Split virus vaccines have the virus disrupted by a detergent, while subunit vaccines are further purified to include only the portion of the pathogen that stimulates the immune system, such as the HA protein of influenza viruses. Today, the main seasonal influenza vaccine available is an inactivated trivalent influenza vaccine (TIV), which includes representative strains for A/H1N1, A/H3N2, and B virus.<sup>21</sup> The specific strains are selected based on the surveillance of the circulating viruses from the previous year.<sup>25</sup> Quadrivalent vaccines, which contain both lineages of B virus, are also available, however these are not yet as widespread.<sup>26</sup>

Pandemic influenza vaccines historically have been developed using the same technology as the inactivated seasonal vaccines. The viruses are grown in the allantoic cavities of embryonated chicken eggs, harvested as liquid, undergo inactivation with formalin or  $\beta$ -propiolactone, and are further purified to remove unwanted proteins and other molecules.<sup>9</sup> However, vaccine development for avian influenzas has been hindered due to the virus being rapidly lethal to eggs, the system in which these viruses are grown.<sup>21</sup> Therefore, the product obtained is poorly immunogenic. An inactivated split-virus influenza A/Vietnam (H5N1) vaccine prepared by Sanofi Pasteur requires two 90  $\mu$ g doses given 28 days apart to stimulate an antibody response in 57% of young healthy adults.<sup>27</sup> For comparison, standard seasonal vaccines include just 15  $\mu$ g of HA protein per strain.

Research toward growing viruses for vaccines in continuous cell lines is ongoing in order to eliminate the need for eggs.<sup>28-30</sup> This would allow for increased reproducibility, reduced risk of animal-derived protein products in the vaccines, and allow individuals allergic to eggs to be vaccinated. Two cell lines are the main focus of research: African green monkey kidney cells (Vero) and Madin-Darby canine kidney cells (MDCK). A comparison study of these two cell lines infected with a human influenza virus identified 55 proteins and 32 proteins, respectively, which were shown to be differentially expressed through 2-dimensional difference gel electrophoresis (2D-DIGE) and nano-liquid chromatography (LC) - electrospray ionization (ESI)-MS/MS.<sup>29</sup> The Vero cells showed a stronger stress response to the virus, which may increase cell apoptosis early before enough product is generated. MDCK cells did not show stress responses. Vaccines produced from both cell lines have been in clinical trials showing similar immunogenicity and safety metrics to traditional egg manufacturing methods.<sup>31-34</sup> In 2012 the FDA approved the Flucelvax (Novartis) vaccine, which uses MDCK cells for manufacture. Further, in August 2016, the FDA approved the use of cell-based candidate vaccine viruses in the production of Flucelvax,<sup>35</sup> which could pave the way for avian influenza vaccines to be produced from these cells.

An additional benefit of producing pandemic avian influenza vaccine viruses in cell lines is that these methods may produce more immunogenic strains. Clinical trials of a Vero cell-derived whole virus H5N1 vaccine have shown that subjects showed protective responses after two 7.5 µg or 3.75 µg doses given 21 days apart.<sup>33-34</sup> However, it may be years before pandemic avian influenza vaccines produced using this method are licensed for widespread use. Therefore, other methods of enhancing the immunogenicity to vaccine antigens need to be developed.

### **Vaccine adjuvants**

Adjuvants are one approach to enhance the immunogenicity to vaccine antigens. Adjuvants are added to vaccines in order to increase the stimulation of the immune response by either

enhancing antigen presentation or providing costimulatory signals.<sup>36</sup> Adjuvants have been called the “dirty little secret” of vaccines by the scientific community due to how they were discovered.<sup>37</sup> In 1930, Glenny and colleagues noticed that after precipitating diphtheria toxoid with aluminum sulfate and injecting the “dirty” vaccine into guinea pigs, there was a much greater immune response than to the toxoid alone.<sup>38-39</sup> Using an adjuvant, the amount of antigen can be decreased (dose-sparing). In addition, adjuvanted vaccines can improve the immune response in populations who respond poorly to vaccines, such as elderly and immunocompromised individuals.<sup>36</sup>

Several types of immunologic adjuvants exist depending on the mechanism used to stimulate the immune response.<sup>40</sup> Inorganic aluminum salts, typically aluminum phosphate and aluminum hydroxide (termed alum), are the most widely used adjuvants in human vaccines.<sup>41</sup> Alum has been shown to activate complement<sup>42</sup> and the Nalp3 inflammasome,<sup>43</sup> but the precise mechanism behind the action of alum adjuvants is unknown. It has been hypothesized that the antigen adsorbs on the alum particles, which prolongs its availability to antigen presenting cells.<sup>41</sup> However, it has also been shown that alum causes inflammation at the injection site, resulting in antigen presenting cells being recruited to the area.<sup>41</sup>

In addition to alum, monophosphoryl lipid A (MPL) is an adjuvant used in licensed U.S. vaccines. MPL is derived from the lipopolysaccharide (LPS) of *Salmonella Minnesota* R595,<sup>44</sup> but has only ~0.1% of the toxicity of LPS.<sup>45-47</sup> MPL works by signaling through Toll-like receptor 4 (TLR4) to induce a balanced Th1/Th2 immune response.<sup>48</sup> MPL generally is used in combination with other compounds as an adjuvant system, rather than alone.<sup>47</sup> As AS04, MPL is adsorbed onto alum and is included in the licensed HPV vaccine Cervarix (GlaxoSmithKline).<sup>48</sup> Additionally, MPL is found with QS21, a plant saponin, in AS02 and AS01, where AS01 also contains liposomes.<sup>47, 49</sup> Most recently, the WHO announced that pilot projects of the Mosquirix (RTS,S/AS01) vaccine against malaria will be conducted in sub-Saharan African countries to assess the efficacy of the vaccine in the field, which may help it get licensed.<sup>50-51</sup>

Oil-in-water emulsion adjuvants are another class that are used, particularly in instances when alum adjuvants have proven insufficient. They are thought to increase the trafficking of DCs and macrophages to the lymph nodes.<sup>41</sup> In addition, they are thought to increase the release of cytokines and chemokines from innate cells at the injection site, thus recruiting B and T cells to the site. MF59 (Novartis), a squalene-based adjuvant, appeared for the first time in a U.S. seasonal flu vaccine (FLUAD) during the 2016-2017 season after being licensed in 2015.<sup>52</sup> Another oil-in-water emulsion adjuvant, AS03 (squalene +  $\alpha$ -tocopherol, GlaxoSmithKline), is included in an H5N1 vaccine in the U.S. National Stockpile in case of a pandemic.<sup>53</sup>

Many other types of adjuvants are being developed with the hope of being able to more finely tune the immune response for each pathogen. The saponin QS-21 has been shown to activate human monocyte-derived dendritic cells and promote expression of IL-1 $\beta$ .<sup>54</sup> Synthetic oligodeoxynucleotides containing unmethylated CpG motifs (CpG adjuvants) target TLR9 and enhance humoral immunity.<sup>55</sup> Cytokine mixtures,<sup>56</sup> bacterial endotoxins, D-tetrapeptide-based hydrogels,<sup>57</sup> and others have also been investigated to direct the immune response.<sup>58</sup>

### **Systems biology in the study of vaccines**

Historically, vaccines have been developed empirically using observational knowledge of natural infections and immunity classically illustrated by Edward Jenner's smallpox vaccine in 1798.<sup>59</sup> Jenner used moderately harmful cowpox to immunize against the much more dangerous smallpox (*Variola*) disease. Jenner obtained this idea through a combination of village folklore about milkmaids not becoming infected with smallpox because of previous exposure to cowpox and a conversation in 1763 with Dr. John Fewster who speculated that cowpox might protect against smallpox.<sup>60</sup> When this approach proved successful, more controlled, and scientific experiments were developed to lessen the pathogenicity of specific disease-causing vaccines.<sup>59</sup> Louis Pasteur first showed the attenuation of infectious pathogens by passage in tissue or cell cultures during the development of a chicken cholera vaccine in the late 1870s.<sup>59</sup> Since then, a

number of successful vaccines have been developed using attenuated pathogens or even just killed pathogens. However, due to the empirical nature of vaccine development, not much was understood about how these vaccines were conferring protection. Still, immunologists found methods to assess the efficacy of vaccines.

Correlates of protection, a measurable immune response that is statistically related and responsible for protection, were identified for each vaccine.<sup>61</sup> Antigen-specific antibody titers against the vaccine have been the gold standard for correlates of protection for most pathogens.<sup>61-62</sup> Vaccine-specific antibody levels are measured through standardized serological methods including ELISA to determine binding antibody titers, as well as neutralization and hemagglutination inhibition (HAI) assays. These methods result in a single value representing the full immune response. For example, following influenza vaccination, a serum HAI antibody level greater than 1:40 dilution against the hemagglutinin protein is considered protective.<sup>62</sup> However, a single value threshold may not be sufficient as a correlate of protection due to the natural variability of human biology. In addition, measuring antibody response may not always be the best or only correlate of protection. T cell response is another form of protection that is currently used for the varicella zoster<sup>63</sup> and Bacillus Calmette-Guerin (BCG)<sup>64</sup> vaccines. CD4+ T-cell proliferation assays are the correlate of protection for the zoster vaccine, while interferon levels produced by CD4+ T cells are measured after BCG vaccination.<sup>64</sup> Identifying correlates that are not based on antibodies tends to be more time consuming, expensive, and difficult to perform and interpret compared to antibody assays.

In response to such limitations and difficulties to identify and measure vaccine correlates of protection, current vaccine research has seen a large push toward systems biology studies to study global immune responses to vaccines. Systems biology is an interdisciplinary approach, typically combining multiple –omics fields, that aims to explain complex interactions between all components in biological systems.<sup>65</sup> This approach (termed systems vaccinology) allows for the mechanisms of vaccines to be better understood in order to develop better vaccines and to assess

the efficacy of current vaccines. One goal of systems vaccinology is to predict vaccine immunogenicity and efficacy without relying on the current correlates of protection that are not necessarily the best indicators of protection.<sup>65</sup>

It is hypothesized that dynamic blood transcriptomes and proteomes will show immune response events that correlate with traditional correlates of protection. The first vaccine to be studied this way was the yellow fever vaccine, YF-17D.<sup>66-67</sup> Considered one of the most successful vaccines ever developed, YF-17D provided a good model vaccine to determine the utility of applying systems approaches to vaccines.<sup>65</sup> Using RNA microarrays, Querec *et al.* identified translation initiation factor EIF2AK4 as being correlated with protective cell-mediated and antibody responses, thus providing a predictive signature.<sup>66</sup> Similar studies for TIV<sup>68-69</sup> and meningococcal conjugate vaccines<sup>70</sup> have also identified specific gene signatures correlated either positively or negatively with ultimate antibody responses. Any of these signatures could potentially be classified as correlates of protection if they pass validation. Most interestingly, very early gene expression patterns have been identified as being associated with later antibody responses.<sup>69, 71</sup> Bucasas *et al.*<sup>69</sup> and Nakaya *et al.*<sup>71</sup> identified interferon signaling and antigen presentation pathways up-regulated within the first 24 hours after vaccination. This is a very significant finding for the area of pandemic vaccines, where early determination of a person's ability to develop long-term protection is beneficial. These systems vaccinology studies have offered insights into how protective immunity is generated by investigating multiple immune system components, including mRNA transcripts, antibody responses, and proteins, to obtain a comprehensive assessment of the response to vaccines.<sup>65, 72</sup>

### **Proteomics in systems vaccinology**

While transcriptomic studies are currently expanding our knowledge base about the response to vaccines, systems vaccinology is largely ignoring the proteomics piece of the puzzle. Transcriptomics and proteomics are closely related in that they measure dynamic expression

patterns in response to stimuli. However, multiple studies demonstrate that mRNA and protein expression do not correlate at a given time or even over time.<sup>73-75</sup> By excluding proteomic data, important information about the immune response and possible correlates of protection are potentially missed.

Initial proteomic studies have taken an almost identical approach to RNA studies and used protein and peptide microarrays. Davies *et al.* printed the entire proteome of vaccinia virus on microarray chips and then probed the chips with serum from vaccinated individuals.<sup>76</sup> Antibodies in the serum bound to proteins on the chip were observed using fluorescent secondary antibodies to obtain a quantitative measurement. Price *et al.* found similar results using both whole protein and peptide microarrays for influenza. In addition, peptide-array reactivity significantly correlated with age and neutralization titer.<sup>77</sup> It also has been proposed that certain biomarkers present prior to vaccination can also predict later vaccine response. Using peptide microarrays, four viral influenza hemagglutinin peptides were identified with expression levels that correlated to the pre-vaccination HAI titer.<sup>78</sup> This allowed for a model that successfully identified “good” and “poor” responders to an influenza vaccine based on their baseline antibody repertoire. It is important to note, though, that these studies tested only the antibody repertoire, a small portion of the immune system’s proteome response, to vaccines.

### **Quantitative Proteomic Methods and iTRAQ**

Gel-based proteomic methods largely dominated the proteomics field until mass spectrometry (MS)-based methods were introduced.<sup>79</sup> MS allows for the high-throughput detection of ionized gas-phase analytes based on their mass-to-charge ratio ( $m/z$ ). Electrospray ionization (ESI) is one available method to ionize the analytes.<sup>80</sup> As ESI ionizes analytes from solution, it can easily be combined with liquid separation methods, such as liquid chromatography (LC).<sup>81-83</sup> This is especially beneficial for highly complex proteomics samples.<sup>84</sup> After ionization, analytes are manipulated by electric and/or magnetic fields in order to separate them by their  $m/z$  for detection.

Tandem mass spectrometry (MS/MS) can also be performed to obtain more structural information about the analytes.<sup>85</sup> In MS/MS, a precursor ion is selected, isolated, and fragmented into product ions, which are then detected. This can be done in time within one trapping analyzer or in space with hybrid instruments containing multiple analyzers in series. In the case of proteomics, the starting sample is typically a mix of peptides derived from enzyme digested proteins. When these peptides undergo MS/MS, sequence information can be extracted from their spectra because peptides fragment at predictable locations, with b- and y-ions being the most common (Figure 1.7).<sup>84</sup> Further, the peptides can then be mapped back onto the proteins from databases in order to determine which proteins were present in the original sample.<sup>86</sup>

**Figure 1.7 Peptide fragmentation locations.**

Currently, proteomics methods are focused on quantitative studies rather than just protein identifications.<sup>87-88</sup> Multiple methods have been developed for quantitation of proteins using MS, each offering benefits and limitations (Figure 1.8).<sup>89</sup> Generally, these methods are divided between label-free and label-based methods. Label-free methods first allowed for the comparison of the same proteins across different experiments in their natural state. The area under the curve obtained as peptides elute or spectral counting are two methods for label-free quantitation,<sup>90</sup> however high reproducibility is required for the different samples to be compared.<sup>91</sup>

**Figure 1.8 Comparison of quantitative proteomic mass spectrometry methods.** Each method indicates when samples are labeled (shown by blue [light] and red [heavy]). The exception is label-free quantitation, which analyzes each sample individually and compares the data using AUC, spectral counting, etc. Samples are labeled *in vivo* in metabolic labeling, combined, and processed for analysis. In enzymatic and chemical labeling, protein extraction occurs prior to labeling. Enzymatic labeling adds the isotopes during digestion. With chemical labeling, the peptides are labeled after digestion. Isobaric tags, a subcategory of chemical labeling, requires LC-MS/MS to generate cleaved tag spectra in the MS<sup>2</sup> for quantitation. Known amounts of spiked heavy peptides are added to unlabeled samples, which allows for a standard curve to be made. This leads to absolute quantitation. Adapted from Thermo.<sup>92</sup>

Stable isotope-labeling methods were developed to overcome the label-free limitations and offer higher accuracy of measurements, but do require additional steps and higher cost. Label-based methods make use of stable heavy isotopes ( $^{13}\text{C}$ ,  $^{15}\text{N}$ ,  $^{18}\text{O}$ ) to produce mass shifts of peptide peaks in the mass spectrum, while maintaining the original isotope pattern.<sup>91</sup> These heavy

isotopes largely do not affect the behavior of the peptides and proteins during chromatography or in the mass spectrometer. Therefore, the relative-abundance ratios (peak intensities) of peptides can be compared between the different labeled samples to obtain quantitative information.

The simplest labeling method involves the spike-in of isotope labeled standards, which allows for absolute quantitation (AQUA). However, heavy-labeled peptides have to be synthesized for each peptide being quantified, which can be costly.<sup>93</sup> Isotope labels can also be covalently linked to the proteins and peptides. In this case, the isotope labels are introduced metabolically, enzymatically, or chemically.<sup>82</sup> Stable isotope labeling by amino acids in cell culture (SILAC) is the most common method for metabolically labeling proteins.<sup>94</sup> SILAC uses  $^{13}\text{C}_6$ -Lys and  $^{13}\text{C}_6$ - and  $^{15}\text{N}_4$ -Arg containing cell media to label proteins *in vivo*. While this reduces the variability by introducing the labels early on, this method is only possible with experiments involving growing cells.<sup>95</sup> Enzymatic labeling introduces either  $^{18}\text{O}$  or  $^{16}\text{O}$  into peptides during proteolysis, so no additional steps are needed.<sup>96</sup> However, these labels lead to small mass shifts, so high-resolution instruments are required. Chemical labeling, however, is the most common approach for label-based proteomics methods, due to the fact that any sample can be labeled.<sup>91</sup> This method involves the derivatization of peptides with isotopically labeled tags. ICAT (isotope-coded affinity tags)<sup>97</sup>, TMT (tandem mass tags)<sup>98</sup>, and iTRAQ (isobaric tags for relative and absolute quantitation)<sup>99</sup> are all different methods that utilize chemical labeling for quantitation and each allow for different multiplexing capabilities. Weaknesses associated with chemical labeling include incomplete labeling reactions and potential for side reactions.<sup>95</sup>

The iTRAQ method is advantageous because it allows for the simultaneous analysis of up to eight different samples within one experiment.<sup>99-100</sup> Each reagent contains a peptide reactive group, balance group, and reporter group (Figure 1.9A), but overall each reagent has the same molecular weight and produce identical mass shifts. The N-hydroxysuccinimide ester portion of the peptide reactive group reacts with primary amines to label peptides with an isobaric tag. Each sample is labeled with a different reagent, containing different distributions of heavy isotopes in

the reporter group, and mixed. Tagged peptides with identical sequences co-elute and are detected as a single precursor ion (Figure 1.9B). Upon fragmentation of a tagged peptide ion, the reporter ions are measured in the  $m/z$  113-121 range of the MS/MS spectrum. The relative intensities of these reporter ions are proportional to the relative abundances of the labeled peptide between the different samples.

The various MS-based quantitative proteomics methods allow for a higher throughput assessment of a system's proteome than previous quantitation methods. By applying an iTRAQ strategy in systems vaccinology studies, a more global and quantitative view of the immune response can be achieved.

**Figure 1.9 iTRAQ labeling method.** (A) General structure of the individual iTRAQ reagents includes the peptide reactive group (right), balance group (middle), and reporter group. (B) Identical labeled peptides co-elute and are detected as one precursor peak in the MS spectrum. After fragmentation, reporter ions are detected in the low mass range of the MS/MS spectrum, which allows for the quantitative information to be extracted.

### Scope of this work

The goal of this dissertation is to develop and optimize a method for assessing the proteomic response in individual immune cells following vaccination and then apply that method to an adjuvanted influenza vaccine clinical trial in order to better understand the mechanism of action of the adjuvant. Chapter II describes the development and optimization of the quantitative

proteomic method to investigate the immune response in purified immune cells across time. The optimized method multiplexed the same cell type at various time points together using 8-plex iTRAQ. This also serves as a proof-of-concept study showing that by analyzing individual immune cell types, more proteins are identified compared to traditional whole blood or PBMC samples, allowing for a more complete picture of the immune response to be obtained. Chapter III discusses the proteomic results obtained from the AS03-adjuvanted H5N1 clinical trial, which used the optimized method developed in Chapter II. A comparison of these proteomic results to results from a transcriptomics study conducted in parallel is also included. These chapters showcase one of the first times quantitative shotgun proteomics has been used to assess the immune response to a vaccine. By doing so, a more complete understanding of the immune response and vaccine mechanism can be obtained.

## CHAPTER II

### A CELL-BASED SYSTEMS BIOLOGY ASSESSMENT OF HUMAN BLOOD TO MONITOR PROTEOMIC IMMUNE RESPONSES AFTER INFLUENZA VACCINATION

#### Introduction

Systems biology is a comprehensive approach to describe complex interactions between multiple components in a biological system.<sup>1</sup> Using high-dimensional molecular approaches, systems biology identifies changes caused by perturbations such as infection or vaccination, combined with extensive computation analysis to model and predict responses.<sup>1</sup> In the context of vaccinology, systems biology offers an approach to dissect the human immune response after immunization by correlating changes in the transcriptome or proteome with antibody or cell-mediated immune responses, in order to make predictions about vaccine efficacy and potentially adverse events, such as pain, headache, fever, and fatigue.<sup>2-3</sup>

Systems biology studies with influenza vaccines have identified modules of genes that positively correlated with protective immune responses.<sup>4-5</sup> For example, interferon-responsive genes that were up-regulated at early time points after TIV positively correlated with robust HAI titers.<sup>4-5</sup> Nakaya *et al.* found that an elevated antibody response to TIV, but not LAIV, correlated with up-regulation of B cell-specific transcripts, including immunoglobulins and the TNFRSF17 surface receptor.<sup>6</sup> Using the Nakaya dataset, Tan *et al.* identified immunoglobulin and complement genes as well as proliferation-associated genes to be predictors of protective antibody production in response to TIV.<sup>7</sup> They concluded that enrichment of these gene sets at 7 days post-TIV vaccination was likely due to an increase of proliferating plasmablasts in subjects with elevated antibody response.<sup>7</sup>

In addition to studying post-vaccination responses, predictive correlates identified prior to vaccination have also been studied. Tsang *et al.* showed that baseline proportions of 126 immune

cell sub-populations in the blood could predict influenza vaccine-induced antibody responses.<sup>8</sup> Furman *et al.* identified several additional baseline predictors of protective immunity, including the frequency of CD8+ T cells and NK cells, as well as multiple differentially expressed gene modules.<sup>9</sup> These included genes associated with: 1) apoptotic pathways; 2) cell survival and proliferation; 3) cell-to-cell signaling; 4) RNA post-transcriptional modification; and 5) carbohydrate metabolism.<sup>9</sup>

Despite insights to the global human immune responses to influenza vaccines obtained from these and other studies, the majority of systems biology studies are limited in scope to total RNA from whole blood or peripheral blood mononuclear cells (PBMC).<sup>4,7-11</sup> Blood is comprised of many hematopoietic cell types that are present in varying proportions (Figure 2.1) and therefore, responses elicited from under-represented cell types are likely masked by those of predominant cells.<sup>12</sup> Nakaya *et al.* observed this when transcription factor XBP-1 was upregulated in sorted B cells, but not PBMC, after TIV vaccination.<sup>6</sup> XBP-1 is necessary for the terminal differentiation of antibody-forming plasma cells, and therefore an important factor for developing protective immunity.<sup>6</sup> Additionally, when utilizing PMBC to monitor the immune response, the contributions of polymorphonuclear (PMN) cells – the prime contributors to innate immunity – are ignored, as these cells are separated out. Furthermore, an immune response represents a highly coordinated effort from multiple hematopoietic cell types – each with their own inherent programming.<sup>13</sup> Therefore, it is vitally important to analyze and model individual immune cell types in response to vaccination.

To develop a comprehensive systems biology model for studying immune responses following vaccination, we developed an efficient protocol to quantitatively analyze five purified immune cell types from human blood that contribute to both innate and adaptive immune responses: T cells, B cells, NK cells, monocytes, and neutrophils. Unlike previous systems vaccinology studies, my protocol uses quantitative proteomics to monitor changes in protein expression prior to and after TIV vaccination. My results reveal that protein expression profiles from each sorted cell type differ

significantly from the profile obtained from PBMC. Comparison of differentially expressed proteins after vaccination with 2011-2012 seasonal TIV further shows considerable differences between PBMC and sorted cells. Together, my data suggest that important cell type-specific information is gained when purified cells rather than PBMC or whole blood are sampled in systems studies.

**Figure 2.1 Breakdown of the components in blood.** Immune cells, found in the leukocytes category represent a very small portion of a blood sample. Additionally, these immune cells have different concentrations compared to one another.<sup>14</sup>

## Methods and Materials

### *Seasonal TIV vaccination of human volunteers and blood collection*

Volunteer recruitment and vaccination protocols for this study were approved by the Vanderbilt Institutional Review Board (IRB#111030 “CLR-03 2011-Immune Cells and Soluble Factors from Healthy Donor”). After obtaining written informed consent, two subjects were vaccinated with a single dose of 2011-2012 seasonal trivalent inactivated influenza vaccine (TIV) (strains included: A/California/7/09 (H1N1), A/Perth/16/2009 (H3N2), and B/Brisbane/60/2008). Blood samples (90 mL) from the two vaccinated subjects were processed prior to vaccination (day 0) and at days 1, 3, and 7 post-vaccination for downstream quantitative proteomic analysis.

### Immune cell isolation

Freshly collected whole blood was fractionated into PBMCs and PMNs over a Ficoll density gradient (GE Healthcare, Marlborough, MA). PBMC and PMN fractions were then subjected to magnetic-activated cell sorting (MACS) to positively select CD3+ T cells, CD14+ monocytes, CD15+ neutrophils, CD19+ B cells or negatively enrich for CD3-CD14-CD15-CD19- NK and mDC (Figure 2.2). MACS-enriched cells were further subjected to fluorescence-activated cell sorting (FACS) to achieve  $\geq 98\%$  purity (Figure 2.2). Recovery of sorted mDC cells was insufficient for proteomic analysis ( $1 \times 10^6$  cells needed) and therefore proteomic analysis was not performed on this cell type.

**Figure 2.2 Flow cytometry analysis of immune cell types purified from human blood.** PMN and PBMC cell fractions from a single representative subject were subjected to CD15+, CD3+, CD19+, and CD14+ positive selection or CD19-CD15-Cd14-CD3- enrichment (top panels) via magnetic sorting (MACS). MACS-enriched cells were stained with a cocktail of antibodies and subjected to FACS (bottom panels) to obtain highly purified neutrophil, T cell, B cell, monocyte, and NK populations for systems analysis.

### iTRAQ experiment preparation

Protein extracts from PBMC and sorted immune cells ( $1 \times 10^6$  cells) from two vaccinated human subjects were prepared by ultrasonating cells in lysis buffer (50% trifluoroethanol 50 mM HEPES). The protein amounts were quantified using a BCA assay. An immune cell common standard (ICCS) control sample composed of protein extracts from PBMC and CD15+ cells (80%

and 20%, respectively, by protein weight) was included in duplicate in all 8-plex iTRAQ experiments. Ten micrograms of protein per sample was reduced by 50 mM tris(2-carboxyethyl)phosphine (TCEP), cysteine blocked by 200 mM methyl methanethiosulfonate (MMTS), and digested with trypsin (1:50 trypsin:protein) overnight.<sup>15-18</sup> The peptides were desalted through solid phase extraction with a reverse phase microtrap column (Michrom BioResources, Auburn, CA). The peptides were resolubilized in 7  $\mu$ L 500 mM triethylammonium bicarbonate. Twelve microliters of iTRAQ reagent (AB Sciex, Framingham, MA) were added to the peptide samples. The labeling reactions were incubated with shaking for 2 h, pooled together, frozen, and lyophilized. The iTRAQ labeled samples were resolubilized in buffer A (5% acetonitrile/0.1% formic acid in water) to 0.5  $\mu$ g/ $\mu$ L and analyzed by MudPIT using an Eksigent 2-D nanoLC pump coupled to a nanoESI-LTQ-Orbitrap XL mass spectrometer (Thermo Scientific, Waltham, MA). The precursor ions were analyzed in the Orbitrap followed by 4 CID fragment ion scans in the ion trap to identify the peptides. The precursor ions were then fragmented by HCD to measure reporter ion intensities in the Orbitrap.<sup>19-21</sup>

#### *Quantitative proteomic analysis*

For each precursor ion, the CID and HCD spectra were merged using *Proteome Discoverer v1.3* (Thermo Scientific, Waltham, MA). The merged fragmentation spectra were searched against a forward and reverse concatenated human Ensembl protein and common contaminants database (gene model 74) using the *Sequest* database search engine running under *Proteome Discoverer*.<sup>22-23</sup> Precursor mass tolerance was set to 20 ppm and fragment mass tolerance to 0.8 Da. iTRAQ modification of N-terminus and  $\epsilon$ -amine of lysines and  $\beta$ -methylthiolation of cysteines were used as static/constant modifications of the peptides. Oxidation of methionine and tryptophan and deamidation of asparagine and glutamine were used as dynamic/variable modifications of the peptides. Protein assembly, reporter ion quantitation, and statistical analysis

were performed with a 5% peptide and protein FDR using *ProteoIQ* v2.61 (Premier Biosoft, Palo Alto, CA).

#### *Comparative and differential analysis*

Prior to differential analysis, missing values and contaminating keratin proteins were removed from the protein lists. A  $\geq 1.25$  fold change (calculated in *ProteoIQ*) in expression between pairwise comparisons (days 0-1, 0-3, and 0-7) was considered significant. Comparative analysis of the proteomic profiles between cell types was performed using Spearman correlation coefficients. Principal component analysis (PCA) was performed in *R* and plotted using the *rgl* package.<sup>24</sup> Hierarchical clustering analysis, dendograms, and heatmaps were generated using *Cluster3.0* and *Java Treeview*, respectively.<sup>25-26</sup> A Unix bash shell command was used to identify differentially expressed proteins shared between individuals and cell types, as well as to create lists of proteins for heat maps.

#### *Visualization of proteins across the human genome*

Genome-wide visualization of relative protein expression from PBMC and each purified immune cell type was generated using the open-source *Circos* software package.<sup>27</sup> The genome location for individual protein data points was mapped using *BioMart*.<sup>28</sup>

#### *Network analysis*

Differentially expressed proteins identified in both subjects after vaccination were imported into *Ingenuity Pathway Analysis* (Qiagen, Alameda, CA) to identify the most significantly affected unique canonical pathways, biological functions, and networks between time points.

## Data Availability

The raw proteomics data and unfiltered database search results are available via the ProteomeXchange Consortium (<http://proteomecentral.proteomexchange.org>) with the dataset identifier PXD001657 and DOI 10.6019/PXD001657.

## Results and Discussion

### Protein quantification from purified cells

Prior to performing quantitative proteomics, protein lysates from PBMC and sorted cells were quantified. The different cell types ( $1 \times 10^6$  cells) generated between 30-80  $\mu\text{g}$  protein/sample (Figure 2.3). Neutrophils contained the highest amount of protein, followed by monocytes, while lymphocytes contained the least. As monocytes and neutrophils are much larger than lymphocytes,<sup>29</sup> it is reasonable to see higher protein amounts from these cell types since the assays were performed based on cell number and not cell volume. Lundberg *et al.* previously showed a correlation between cell size and protein expression levels.<sup>30</sup> To remove this bias from later analyses, experiments were done on normalized protein weights rather than cell number.

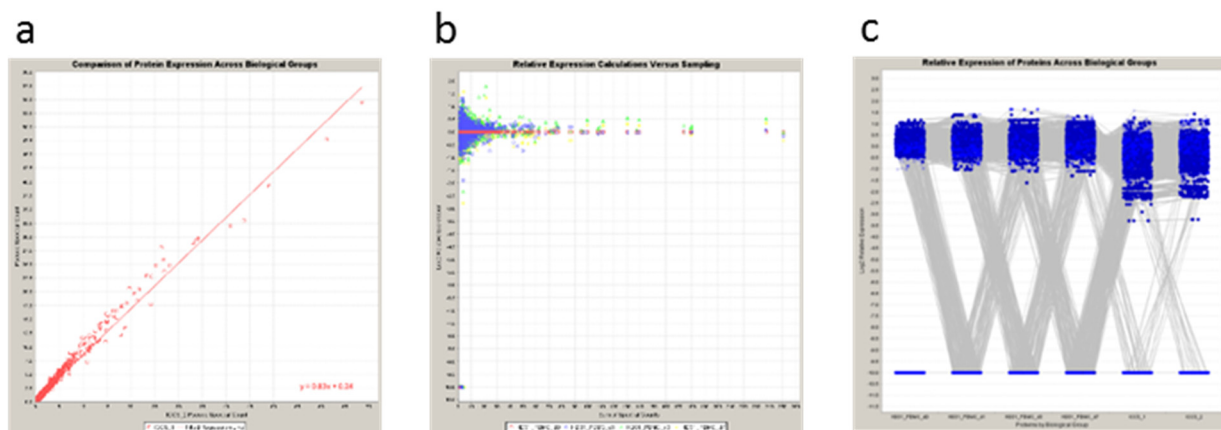

**Figure 2.3 Adequate protein quantity is obtained from sorted immune cells for proteomics applications.** Total protein isolated from sorted immune cells ( $1 \times 10^6$  each cell type) from a single vaccinated subject was quantified.

### Evaluation of proteomics data quality

A slope of the regression line  $>0.8$  between the technical replicates of the common control (ICCS) based upon pseudospectral counts was required as a quality control threshold (Figure 2.4A). A plot of  $\log_2$  fold changes against pseudospectral counts was used to assess the effect of

sampling over the observed fold changes. The symmetric distribution of  $\log_2$  fold changes versus pseudospectral counts suggests the differential expression analysis was unbiased by protein abundances (Figure 2.4B). Distribution of relative expression across different samples was visualized using cluster dot plots to see if obvious differences occurred between samples (Figure 2.4C). The ICCS iTRAQ channels showed a wider range of expression values (last two columns) compared to the purified cell types, likely due to being a compilation of cell types. Experiments where the purified cell types showed similar protein expression distributions were considered in compliance.

**Figure 2.4 Proteomics quality control.** (a) Scatter plot showing the protein abundances measured in two technical replicates of the ICCS common control. Each dot represents an individual protein. X-axis represents the protein abundances measured in replicate 2. Y-axis represents the protein abundances in replicate 1. (b) Scatter plot showing the distribution of fold changes of proteins with respect to their abundances. Each dot represents an individual protein. X-axis represents protein abundance. Y-axis represents fold changes. (c) Cluster dot plot showing the distribution of fold changes in different iTRAQ channels. Each dot represents an individual protein and the lines represent patterns of expression change.

### *Comparison of two iTRAQ labeling strategies*

Two iTRAQ labeling strategies were tested to determine the optimal pooling strategy for detecting proteomic changes after vaccination (Figure 2.5). In strategy 1, all six cell types at a single time point were multiplexed into one experiment. In strategy 2, all four time points from a single cell type were multiplexed into an experiment. Strategy 1 is advantageous because the

technical experimental variation between cell types at each time point would be minimized. However, since the MS/MS method selects peptides for fragmentation and therefore identification and quantitation based upon their abundance in the sample proteins present in higher amounts across the samples would be preferentially quantified. Thus, differentially changing proteins with low expression from a single cell-type might not be quantified. Further, by increasing the complexity of the sample pool through multiplexing lysates from six different cell types, co-fragmentation of co-eluting peptides might cause an increase in iTRAQ signal interference, and therefore possibly negate the effects of purifying the cells. In contrast, strategy 2 does not have the potential signal interference problems because the sample complexity is reduced due to similar proteomes being pooled together. This would also ensure quantitation of a larger fraction of cell type-specific proteins. However, strategy 2 may detect artifacts due to technical experimental variation.

**Figure 2.5 Two iTRAQ strategies for quantitative proteomic analysis of immune cells after vaccination.** Experimental design. In strategy 1, multiple immune cell types from one time point were multiplexed together in the experiment. In strategy 2, different time points from the same immune cell type were multiplexed together. An immune cell common standard (ICCS) was used to normalize reporter ion intensities across the experiments.

The two strategies were compared with both unsupervised hierarchical clustering and PCA (Figure 2.6). In strategy 1, the cell types did not completely cluster together in the unsupervised hierarchical clustering analysis. However, the cell types in strategy 2 did cluster together. Additionally, the heatmap shows distinct protein expression patterns for the different cell types in strategy 2, while strategy 1 has very similar patterns for the cells derived from the PBMC fraction (monocytes, NK cells, B cells, and T cells). The neutrophil samples show a relatively different clustering compared to the other cell types, as they originate from the PMN blood fraction. This is also observed in the PCA plots (Figure 2.6B). There is poor clustering of the cell types in strategy 1 and the different cell types fail to separate. In contrast, strategy 2's PCA plot shows distinct clustering of the cell types (Figure 2.6B). The neutrophil samples clustering the furthest away indicating their different protein expression. The possibility of these results being caused by batch effects was discounted as the samples from each individual iTRAQ experiment using strategy 1 did not cluster together by either hierarchical clustering or PCA. Overall, strategy 2 produced cell-type specific clustering and protein expression patterns by both methods, while strategy 1 did not. Therefore, strategy 2 was considered the optimal approach and employed for the remaining proteomic analysis.

**Figure 2.6 Comparison of global proteome analysis for two iTRAQ strategies.**(a) Unsupervised hierarchical clustering analysis and (b) PCA of pseudo-spectral counts from one subject generated using strategy 1 (left panels; 5,676 proteins, filtered to remove zero values and contaminating keratins) or strategy 2 (right panels, 3,852 proteins, filtered to remove zero values and contaminating keratins) reveals that cell-types cluster together and display distinct cell-type specific patterns of protein expression using strategy 2, but not with strategy 1.

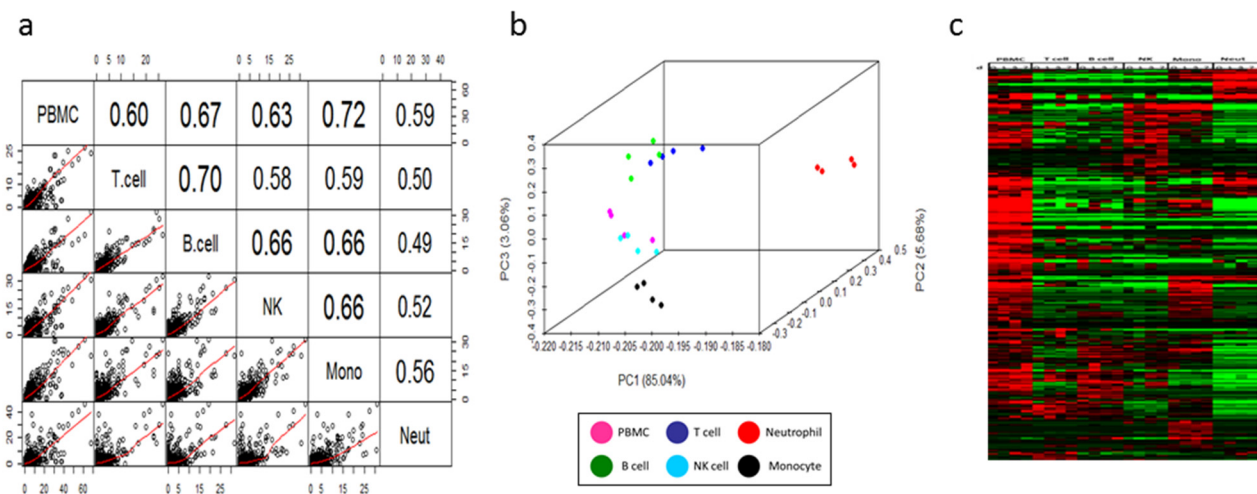

### *Proteomic profiles of two TIV-vaccinated subjects*

The proteomes of PBMC and five purified immune cell types from two subjects before (day 0) and after TIV vaccination (days 1, 3, and 7) were analyzed by MS to identify changes in the immune response. Approximately 7000 proteins were identified in 44 protein samples (Table A-1). After removing zero values (identified but not quantified proteins) and contaminating keratins, approximately 4000 proteins from each subject were retained for further analysis (Table A-2 - Table A-3). The PBMC and purified immune cell baseline (day 0) proteomes from one vaccinated subject (HD31) plotted over the length of the human genome showed activity across the majority of the genome indicating unbiased genome coverage (Figure 2.7). This plot also showed distinct proteomic profiles between the different cell types at baseline. The results agreed with the observations made during the iTRAQ pooling strategies experiments.

**Figure 2.7** Circos representation of baseline proteomic profiles of PBMC and individual immune cell types. Bars on the outside of the circle represent individual chromosomes. The heat-map color scaling parameter was set to “scale\_log\_base = 10” to allow for optimal color space.

Pair-wise comparisons of baseline proteomic data (day 0) from one subject showed poor correlation between PBMC and sorted cells (Figure 2.8A). The highest correlation was observed between monocytes and PBMC. However a Spearman correlation coefficient of 0.72 suggests a poor correlation. PCA revealed that all cell types clustered distinctly from each other (Figure 2.8B). Semi-supervised hierarchical clustering analysis of identified proteins showed that each cell type displayed a distinct protein expression profile that differed from both PBMC and the other cell types (Figure 2.8C). This indicates that the immune cell purification strategy employed allowed for the identification of proteins that are masked in the PBMC sample. As current vaccine studies use either whole blood or PBMCs to assess the vaccine response, these low abundant proteins would be missed in the analyses and therefore a full picture of the response to vaccines would not yet been synthesized.

**Figure 2.8 Proteomic analysis of purified immune cells in subject HD31 after TIV vaccination. (a)** Pair-wise comparison of day 0 protein profiles (3,852 proteins, filtered to remove zero values and contaminating keratins) from subject HD31 shows that proteomes of sorted cells correlate poorly with PBMC. **(b)** PCA of protein profiles from subject HD31 at four time points shows that purified immune cell types cluster into distinct groups. **(c)** Semi-supervised hierarchical clustering analysis of relative protein expression from a vaccinated individual reveals that purified immune cells have distinct proteomic expression profiles compared to PBMC. Data was centered across protein and cell type; red = up, black = no change, green = down.

**Figure 2.9 Proteomic analysis of purified immune cells in subject HD30 after TIV vaccination. (a)** Pair-wise comparison of day 0 protein profiles from subject HD30 shows that proteomes of sorted cells correlate poorly with PBMC. **(b)** PCA of protein profiles from subject HD30 at four time points shows that purified immune cell types cluster into distinct groups. **(c)** Semi-supervised hierarchical clustering analysis of relative protein expression from a vaccinated individual reveals that purified immune cells have distinct proteomic expression profiles compared to PBMC. Data was centered across protein and cell type; red = up, black = no change, green = down.

The proteome of the second vaccinated subject (HD30) also showed distinct protein expression profiles among the different cell types and a lack of correlation between the different cell types (Figure 2.9). However, PCA of the proteomics data for both subjects showed that while the cell types at all time points clustered similarly on a per-subject basis, the cells from the two subjects did not cluster together (Figure 2.10). Overall, intra-individual variability in the cell type responses from subject HD31 is smaller than the intra-individual variability in subject HD30 and the inter-individual variability between the two. This indicates that either different subsamples of the proteome were identified from each subject or the same subsample of identified proteins were identified in both subjects but were responding at different levels. Either possibility is likely due to biological variability between the proteomes of the two subjects. It has been estimated that 20-40% of immune variation is due to heritable factors and 5% to intrinsic factors,<sup>31</sup> leaving a large portion of immune variation due to environmental and other factors.<sup>32</sup> While these estimates are based on leukocyte population subsets and function, it can be extrapolated that this variation also occurs on the protein level as the proteins do the work in the cell.

**Figure 2.10 Principal component analysis reveals poor correlation of proteomes between subjects.** Proteins (5,304 total proteins, filtered to remove zero values and contaminating keratins) from subject 1 (HD31; large circles) and subject 2 (HD30; small circles) were clustered in the same experiment. PC1 = 77.19%, PC2 = 6.99%, PC3 = 5.23%.

Previous studies investigating inter-individual proteome variability in various biological matrices showed protein abundance variance ranging between 10% and 148%.<sup>31-33</sup> While none of these studies investigated the variability of purified cell populations, one study measured the mean variation to be 28% in the PBMC proteome of 24 individuals.<sup>31</sup> Our study of two subjects showed average CV values ranging between 43-57% for the pseudospectral counts of individual immune cell types at day 0. These higher CV values are likely due to a small sample size. However, the maximum protein CV for the cell types was 133%, which is in agreement with previous reported values.<sup>31-33</sup> This high variability may pose a challenge when identifying shared protein responses. Indeed, less than 20% of differentially expressed (DE) proteins responding in the same direction were shared between both subjects for most cell types and time points (Table 2.1). The proof-of-concept study showed additional unique protein identifications on a cell-type level obtained from purifying immune cells for proteomic vaccine studies. With only two subjects, the statistical power is not sufficient to allow for biological conclusions, only observations. A larger sample size would be needed to extract specific biological information.

**Table 2.1 Shared DE proteins.**

Cell type	Time point	HD30		HD31		Shared

*Differential analysis of proteins from two TIV-vaccinated subjects*

For comparison of proteomic changes in PBMC and sorted immune cells, DE proteins  $\geq 1.25$  fold after vaccination were investigated. While standard methods for determining fold change typically use a 2x fold change threshold, this level failed to identify significant numbers of shared DE proteins between both subjects. I hypothesize that this is likely due to iTRAQ under-reporting fold changes that has been previously reported.<sup>34</sup> By choosing the 1.25 threshold, comprehensive lists of DE proteins from each cell type that were shared between both subjects at each time point were obtained. There was little correlation between PBMC and purified immune cell types when comparing DE proteins (Table 2.2). The greatest overlap occurred between monocytes and PBMC at day 3 with 25% of the proteins being shared. This is expected as monocytes and PBMCs had high Spearman correlation coefficients as discussed earlier. Interestingly, this comparison also indicates a time trend in the number of DE proteins identified, with the most identified at day 3 in all cell types.

**Table 2.2 Comparison of differentially expressed proteins in PBMC and individual immune cell types.**

	Day 0-1		Day 0-3		Day 0-7	
	# proteins identified *	# (%) shared with PBMC	# proteins identified *	# (%) shared with PBMC	# proteins identified *	# (%) shared with PBMC
<b>PBMC</b>	585	-	863	-	865	-
<b>T cell</b>	922	41 (7.0%)	1085	132 (15.3%)	685	74 (8.6%)
<b>B cell</b>	732	75 (12.8%)	782	40 (4.6%)	612	89 (10.3%)
<b>NK</b>	704	71 (12.1%)	799	141 (16.3%)	698	129 (14.9%)
<b>Monocyte</b>	526	36 (6.2%)	652	222 (25.7%)	534	163 (18.8%)
<b>Neutrophil</b>	291	48 (8.2%)	325	84 (9.7%)	322	42 (4.9%)

Circos was used to plot DE proteins over the length of the human genome and to visualize overlap of DE proteins at three time points after TIV vaccination (Figure 2.11). The plots showed a lack of substantial overlap in DE proteins between PBMC and each cell type at each time point, as indicated by there being more grey lines than red.

**Figure 2.11 Visualization of differentially expressed proteins in PBMC and individual immune cell types.** Circos plots of DE proteins from a vaccinated subject at (a) day 1, (b) day 3, and (c) day 7 post-TIV vaccination. For each cell type, the colored bar on the outer circle represents the entire human genome; segments within the bars divide the genomes into chromosomes. Red lines indicate DE proteins that are shared between PBMC and purified immune cell types. Grey lines indicate DE proteins that are shared between the purified immune cell types.

Finally, semi-supervised hierarchical clustering revealed little overlap in the shared DE proteins from each cell type at each time point (Figure 2.12). This analysis suggest variability between the two subjects' innate immune cell proteomes. This is most noticeable in NK cells at day 7, where a subset of proteins are up-regulated in one donor while down-regulated in the second donor (Figure 2.12C). However, the majority of the shared DE proteins are responding in the same direction just at different intensities when comparing between donors. Histone proteins are one example of this, as they are largely up-regulated in the majority of the cell types for both donors. This is expected because histones have been observed to increase circulation in response to stress, infection, and inflammation.<sup>35</sup>

**Figure 2.12 Unique modules of proteins are differentially expressed in each immune cell type after TIV vaccination.** Log<sub>2</sub> fold change values of shared DE proteins in each cell type from both subjects were clustered at (a) day 1 (196 proteins), (b) day 3 (263 proteins), and (c) day 7 (199) proteins post-vaccination. Very little overlap of differentially expressed proteins is observed between cell types; red = up, yellow = no change, blue = down. B cell data was derived from only one subject due to insufficient recovery of B cells from the second subject.

Lists of significant DE proteins were functionally analyzed using Ingenuity Pathway Analysis (IPA) to identify the most significant biological interactions following vaccination. The top network identified showed unique biological networks induced in each cell type and time point. These results support the observed different responses from these purified immune cells (Figure 2.13- Figure 2.15). The network annotations and the top canonical pathways identified from each cell type and time point were determined (Table A-4). Each cell type had different function annotations

derived from the networks. Most of these were generic functions, such as cellular assembly, cell cycle, and cellular movement. However, inflammatory response and immune cell trafficking were identified for monocytes at day 1 and NK cells at day 3, respectively, showing that proteome analysis of the immune response of individual immune cell populations can identify important immune responses.

## **Conclusions**

The goal of this study was to develop methods and establish protocols that can be used in future systems vaccinology studies. By utilizing an efficient cell-sorting protocol, sufficient numbers of five immune cell types purified from freshly collected human whole blood were obtained for quantitative proteomic analysis. Additionally, this study optimized the strategy to generate and analyze the quantitative proteomics data. Differential analysis for each human primary immune cell type revealed unique proteomic expression profiles as well as changing biological networks during the early response after vaccination. The methods and strategies developed in this project provided a unique and important opportunity to investigate the quantitative and qualitative differences between human PBMC and individual immune cell types. Only a small fraction of DE proteins identified in the purified immune cell types were also identified in the PBMC fraction. Thus, by analyzing each cell type individually, cell-specific proteomic contributions to the immune response following vaccination were identified. This cell type-specific information, coupled with unbiased systems biology approaches, provides a more comprehensive and robust approach to monitor and eventually model vaccine and infectious disease responses. The approach developed in this pilot project will help guide future systems biology studies aimed at modeling and predicting complex responses to vaccines and vaccine components involving interactions between multiple cell types.

## CHAPTER III

# QUANTITATIVE PROTEOMIC ANALYSIS OF HUMAN IMMUNE CELLS IN RESPONSE TO AS03-ADJUVANTED H5N1 VACCINATION

### Introduction

Developing vaccines against highly pathogenic avian influenza H5N1 is a critically important public health priority due to the high morbidity and mortality associated with influenza infection.<sup>1</sup> However, vaccine development has been hindered by the poor immunogenicity of the H5N1 HA protein when compared with seasonal influenza vaccines.<sup>2</sup> Oil-in-water emulsion adjuvants have demonstrated great promise in enhancing antibody responses at low antigen doses.<sup>3-4</sup> Adjuvant system 03 (AS03)<sup>5-6</sup>, an  $\alpha$ -tocopherol-based oil-in-water emulsion adjuvant, is one such adjuvant. Alpha-tocopherol, an isoform of vitamin E, is a fat soluble antioxidant that works in the glutathione peroxidase pathway to disable the production of free radicals in tissues.<sup>7</sup> Dietary vitamin E supplementation has been shown to aid the immune response, particularly with earlier antibody production to certain pathogens and neutrophil and macrophage phagocytosis and chemotaxis.<sup>8-</sup>  
<sup>11</sup> However, little is known about the benefits of vitamin E as an injectable. The other main ingredients in AS03 are squalene and polysorbate 80 (polyoxyethylene sorbitan-20 monooleate).<sup>5</sup> Squalene is a triterpene collected from shark liver, but also is produced in human liver. It is an essential molecule used for the synthesis of cholesterol, vitamin D, and other steroid hormones and is commonly used in many cosmetics, medications, and other adjuvants.<sup>3</sup> Finally, polysorbate 80 is an emulsifier used in the pharmaceutical and food industries to stabilize aqueous formations.<sup>3</sup>

AS03 has been shown to markedly enhance antibody responses.<sup>3-4</sup> HAI and neutralizing (Nt) antibody titers were significantly increased following two doses of an AS03-adjuvanted H5N1 inactivated, split-virion vaccine, including when dose-sparing vaccines were used (Figure 3.1).<sup>3-4</sup>

The geometric mean titers (GMTs) showed that an adjuvant effect was observed after both doses, but especially after the second. Overall, the addition of the adjuvant allowed for lower amounts of antigen per dose and more protection while being generally well tolerated, with few severe reactions and adverse events.<sup>4-5, 12-17</sup>

**Figure 3.1. AS03-adjuvanted H5N1 vaccination enhances the antibody response.** (A) Homologous Hemagglutination-inhibiting and (B) neutralizing antibody titers in human volunteers after two administrations of a nonadjuvanted or an AS03-adjuvanted H5N1 vaccine. Different doses of influenza antigen were used (from 3.75 to 30 µg).<sup>3</sup>

AS03 has also been shown to increase the frequency of H5N1-specific memory B cells and CD4+ T cell responses, and to induce both cross-reactive antibody and CD4+ T cell responses when administered with H5N1 vaccine.<sup>16</sup> In mouse models, AS03 increased production of monocyte- and neutrophil-recruiting chemokines, promoted the migration of antigen presenting cells to the draining lymph nodes, and enhanced antigen uptake by monocytes.<sup>15</sup> Recently, it was reported that injection of AS03 in rabbits induced a transient inflammatory response as measured by an increase in neutrophil number in the blood.<sup>17</sup> Additionally, early changes in cytokine and chemokine levels after AS03-adjuvanted H1N1 vaccination were attributed to mouse

monocytes.<sup>18</sup> While AS03 enhances the immune response to H5N1 vaccine antigens, the underlying molecular mechanisms are still poorly understood.

One of the concerns regarding the H5N1 vaccines is safety since higher doses are required to elicit a protective response. AS03-adjuvanted vaccines are well tolerated in the healthy adult population, although there are more incidences of local and systemic reactogenicity, such as injection site pain, muscle ache, headache, and fatigue.<sup>3</sup> A concerning discovery, however, was an increased incidence of narcolepsy in patients aged 4-19 after receiving Pandemrix™, a monovalent H1N1 vaccine adjuvanted with AS03 licensed in Europe for the 2009-2010 influenza season.<sup>19-20</sup> Epidemiologic studies indicated a 6 - 13-fold increased risk among the vaccinated, compared to nonvaccinated adolescents.<sup>21</sup> However, a recent study implicates antibodies to the influenza nucleoprotein as the narcolepsy cause, due to their cross-reactivity with human neural hypocretin receptor 2.<sup>22</sup> However, the possible contribution of adjuvants to autoimmune diseases and general safety of adjuvants remain a concern.<sup>23</sup> These findings demonstrate the necessity in comprehensively understanding the mechanisms of action of AS03.

Systems vaccinology allows the human immune response to be comprehensively studied by combining –omics analysis with humoral and cell-mediated immune responses to increase our understanding of the mechanisms by which vaccines and adjuvants confer protection.<sup>24-28</sup> Such studies typically focus only on transcriptome analysis. However, a comprehensive systems vaccinology approach that understands both transcriptomics and proteomics could enhance the understanding of vaccine responses.

We developed a systems biology approach to study the transient immune response following vaccination with a seasonal, inactivated influenza vaccine (trivalent) at the individual primary immune cell type-level.<sup>29</sup> This cell-based approach provided a more comprehensive understanding of the human immune response to vaccination compared to using PBMCs.<sup>29</sup> Additionally, we analyzed both transcriptomic and proteomic responses to a seasonal influenza vaccine.<sup>29</sup> Using the same immune cell-based approach, a randomized, double-blinded,

controlled, Phase I prospective clinical trial to assess the molecular immune responses of an intramuscular split-virus (SV), influenza A/H5N1 (A/Indonesia/05/2005) vaccine given with or without AS03 adjuvant was conducted. Here the changes in the immune cell proteome in responses to these well tolerated vaccines are assessed.

## Methods and Materials

### *Clinical study design*

Twenty healthy adult volunteers aged 19 – 39 years were enrolled in a randomized, double-blinded, controlled Phase I clinical trial designed to determine safety, reactogenicity, and immunogenicity of an inactivated subvirion monovalent influenza A/H5N1 (A/Indonesia/05/2005) vaccine given with or without the AS03 adjuvant. Each subject received two 0.5 mL intramuscular injection doses of 3.75 µg HA per dose with either PBS (SV-PBS) or AS03 adjuvant (4.86 mg polysorbate 80, 11.86 mg α-tocopherol, and 10.69 mg squalene) (SV-AS03) 28 days apart (vaccine product description in **APPENDIX B**). Permuted block randomization with random block sizes of 2 and 4 were applied to improve balance between the vaccine groups. All protocols and consent forms were approved by the Vanderbilt University Institutional Review Board (IRB# 120404 "VTEU 02-2011- A Randomized, Double-Blinded, Controlled, Phase I Study in Healthy Adults to Assess the Safety, Reactogenicity, and Immunogenicity of Intramuscular Subvirion Inactivated Monovalent Influenza A/H5N1 Virus Vaccine Administered With and Without AS03 Adjuvant: Standard and Systems Biology Analyses (DMID 10-0074)").

Peripheral blood samples (100 mL) were collected on days -28, -14, and 0, prior to the first vaccine dose for baseline assessment, and days 1, 3, 7, and 28 post-vaccination for serology, RNA-seq,<sup>30</sup> and proteomics analysis. A final blood sample was collected on Day 56 (28 days after the second vaccine dose) for serological analysis only (see **APPENDIX B**).

### *Immune cell purification*

Purified immune cell populations were isolated from whole blood samples as previously described in Chapter II and published protocols.<sup>29</sup> Briefly, PBMC and PMN fractions were isolated using a Ficoll-paque PLUS (GE Healthcare) separation. These fractions were subjected to magnetic bead separation followed by FACS on a BD FACSAriaIII flow cytometry to acquire  $\geq 98\%$  pure cell populations of neutrophils, monocytes, NK cells, B cells, and T cells for proteomic analysis.

### *Immune serologic assays*

H5-specific HAI and Nt assays were performed at Days 0 (prior to first vaccination), 1, 3, 7, and 28 (prior to the second vaccination) after the initial vaccine dose and 28 days (Day 56) after the second vaccine dose.<sup>31</sup> Titers below the limit of detection (1:10) were given a value of 1:5 prior to statistical analysis. The proportion of subjects achieving serum HAI and Nt antibody titers of 1:40 or greater, and a 4-fold or greater increase in antibodies were calculated for each time point.

### *Quantitative proteomic analysis*

Quantitative mass spectrometry was performed on protein extracts from sorted immune cells as previously described.<sup>29</sup> Briefly, protein extracts were obtained using a modified lysis buffer (50% trifluoroethanol 50 mM HEPES)<sup>32</sup> and quantified by BCA analysis.<sup>33</sup> Due to insufficient amount of collected protein, 17 samples were removed from analysis at this stage (Table 3.1). An immune cell common standard (ICCS) control sample was prepared using 80% PBMC and 20% neutrophil protein extracts (by weight) and included in all iTRAQ experiments as a reference channel. For each subject and cell type, 10  $\mu\text{g}$  of reduced, alkylated, and trypsinized protein extracts were labeled with 8plex iTRAQ tags (AB Sciex), pooled, and analyzed by MudPIT using an Eksigent 2-D nanoLC pump coupled to a nanoESI-LTQ-Orbitrap XL mass spectrometer

(Thermo Scientific).<sup>29</sup> Precursor ions were analyzed in the Orbitrap followed by 4 CID fragment ion scans in the ion trap for peptide identification. The precursor ions were then fragmented by HCD to measure the reporter ion intensities in the Orbitrap.<sup>29</sup>

**Table 3.1 Proteomics samples for which no iTRAQ results were reported due to insufficient amounts of protein**

<b>Subject ID</b>	<b>Cell Type</b>	<b>Study Day</b>
<b>A</b>	B cells	Day -14
<b>A</b>	T cell	Day 3
<b>F</b>	B cells	Day 3
<b>H</b>	B cells	Day -28
<b>H</b>	B cells	Day 0

<b>N</b>	NK cells	Day 28
<b>O</b>	B cells	Day -14
<b>O</b>	T cells	Day -14
<b>Q</b>	NK cells	Day 1

#### *Quality Control of Protein Samples*

Two *S. cerevisiae* proteins (enolase and alcohol dehydrogenase) were added to each sample prior to digestion to act as markers for errors in digestion and iTRAQ labeling. Prior to iTRAQ labeling, 1 µg of each the trypsin-digested protein samples was combined with 0.100 fmol glu-1-fibrinopeptide B (glufib) and run on an LTQ mass spectrometer (Thermo Scientific) as quality control. Previously, the stability of the instrument was assessed for its ability to handle the number of samples (**APPENDIX C**). The raw files were converted to mzxml files and searched against the human protein database using *X!Tandem* within the *Global Proteome Machine* (GPM).<sup>34</sup> Samples where the internal standards were identified and showed similar protein numbers to the ICCS control samples were deemed sufficient for iTRAQ labeling and further analysis. Samples that

were outside of the acceptable limits were checked by visual inspection, re-quantified by BCA, re-digested, and re-checked for compliance.

Each iTRAQ experiment was assessed for consistency as well. The reporter ion intensities for all identified peptides of the two yeast proteins were compared within each subject level experiment. Additionally, the pseudo-spectral counts for yeast proteins as a whole were compared across all 20 experiments for each cell type. Samples that showed values inconsistent with others of the same cell type were checked statistically to determine if they were true outliers and re-analyzed if there was enough material.

### *Peptide and protein quantitation*

The CID and HCD spectra were merged for each precursor ion, using *Proteome Discoverer v1.3* (Thermo Scientific). The merged spectra were searched against a forward and reverse concatenated human Ensembl protein database containing 169,816 sequences (gene model 74) using the *Sequest* database search engine within *Proteome Discoverer*.<sup>35-36</sup> The precursor mass tolerance and fragment mass tolerance were set to 20 ppm and 0.8 Da, respectively. Static modifications of the peptides were set to iTRAQ modification of N-terminus and  $\epsilon$ -amines of lysines and  $\beta$ -methylthiolation of cysteines. Additionally, oxidation of methionine and tryptophan and deamidation of asparagine and glutamine were used as dynamic modifications.

Protein assembly, reporter ion quantitation and statistical analysis were performed with a 5% peptide and protein FDR using *ProteoIQ v2.61* (Premier Biosoft). Peptide intensities within each 8-plex iTRAQ experiment were normalized so that the sum of reporter ion intensities was the same across all channels within the experiment. For each 8-plex iTRAQ experiment, protein level quantifications were calculated for each experimental channel by calculating the median of the  $\log_2$  ratios (experimental channel intensity divided by the ICCS reference channel intensity) for all assigned peptides. The ICCS channel was chosen as reference after comparing the number of quantitative values obtained when it was used as a reference versus Day 0 as a reference (see

**APPENDIX B).** Peptides with missing experimental or reference reporter ion intensities or with intensities below the threshold (intensity < 10) were not included in the median calculations. Indistinguishable proteins with identical median ratios across all subjects and time points were collapsed into one representative Ensembl protein ID with the longest protein sequence.

### *Analysis datasets*

PCA and 1-Spearman correlation distance were used to identify outlying samples (Figure B-1). Seventeen samples, including 4 baseline samples, were flagged as strong outliers based on their placement compared to other cell type samples (Table 3.2). Among these outliers, 7 (41%) were attributable to one neutrophil iTRAQ experiment.

**Table 3.2 Outlying proteomics samples**

<b>Subject ID</b>	<b>Experiment ID</b>	<b>Cell type</b>	<b>Study Visit Day</b>
<b>A</b>	A_NK_3	NK-cells	Day 3
<b>B</b>	B_Neu_5	Neutrophils	Day 28

<b>N</b>	N_Neu_4	Neutrophils	Day 7
<b>R</b>	R_B_5	B-cells	Day 28
<b>R</b>	R_Mono_2	Monocytes	Day 1

Protein ratio distributions across samples were median-normalized within the cell type group to reduce systematic variability between the iTRAQ experiments (see **APPENDIX B**) (Figure B-2

- Figure B-3). For multivariate data visualization, missing protein ratios within cell type were imputed using the k-nearest neighbors algorithm (k=5) using the *impute* package in R (version 1.34.0). Proteins identified in at least 75% of samples within each cell type were considered and only samples for which at least 20% of proteins were non-missing were included in the imputation step. Resulting imputed per-cell type data matrices were also merged to generate a combined set (all cell types together) using zero log<sub>2</sub> ratios to align disparate proteins between cell types.

The Ensembl protein database (Ensemble Version 74) was clustered using CD-HIT software (Version 4.6.1, 08/27/2012) to derive a set of protein families based on 50% protein sequence identity. One representative Ensembl protein ID with the longest protein sequence was selected as the protein family name.

### *Significant Proteins*

Differentially abundant (DA) proteins were identified through the use of an exact two-sided 2-sample permutation test of the mean difference (*coin* R package, version 1.0.23) for each post-vaccination day and cell type combination, if proteins had at least 3 non-missing fold changes for each treatment group. Proteins were considered significant if  $p \leq 0.05$  and the mean treatment fold changes differed by 1.2 fold. Significantly DA proteins and subjects were clustered by their baseline log<sub>2</sub> fold change values using pairwise uncentered Pearson correlation distances and complete linkage clustering. Proteins missing from individual samples were given a value of 0.

### *Gene set enrichment analysis*

Protein accessions were mapped to their corresponding Ensembl Gene IDs. Gene sets and databases were obtained from the KEGG database (version 70.0) and MSigDB (Version 4.0). The *goseq* package in R (version 1.12.0) was used to evaluate gene set enrichment using the hypergeometric distribution to assess significance with the Benjamini-Hochberg correction

applied to adjust for multiple testing.<sup>37</sup> Gene sets with a FDR of  $\leq 0.05$  that contained genes encoding for at least two significant protein families were considered significantly enriched.

#### *Protein-protein interaction networks*

Uniprot IDs and gene symbols for the DA proteins were obtained using the Uniprot retrieve/ID mapping tool. Known human-human and human-influenza A protein-protein interactions were extracted from the IntAct database. The list of interactions was filtered for nodes with a distance of 1 to significantly DA proteins and the networks were visualized using *Cytoscape* (version 3.1.1).

#### *Regularized logistic regression analysis*

A regularized logistic regression model was fit for monocytes (day 1, 3, 7, and 28) and neutrophils (day 1 and 3) to identify protein responses that are correlated with seroprotection (HAI  $\geq 1:40$ ) at any post-vaccination day using the *gimnet* R package (version 2.0-2). Only these cell types were included because they had a sufficiently large number of protein families with non-missing values for at least 9 of the subjects in each treatment group. An elastic net regularization step (combination of L1 Lasso and L2 ridge penalization,  $\alpha=0.5$ ) was included to avoid overfitting. Leave-one-out cross validation was used to determine the optimum parameters which minimized the mean misclassification error between seroprotection response groups.

## **Results and Discussion**

#### *Protective antibody responses*

HAI and Nt antibody titers were determined in order to assess the protective response obtained from each vaccine. Titers did not increase from baseline during the first 7 days after vaccination in either SV-AS03 or SV-PBS groups (Figure 3.2A). At day 28, there was no significant difference in the mean HAI GMT between groups, with no subjects showing an HAI response in the PBS group, while one subject in the SV-AS03 group exhibited an HAI titer  $\geq 1:40$  and a  $>4$ -fold rise in

titer (Figure 3.2B). By day 56, 9 subjects in the SV-AS03 group achieved seroconversion and seroprotection for HAI titers, while none of the SV-PBS group subjects reached seroprotection titers, resulting in a significant difference between the two groups ( $p < 0.001$ ). For the Nt assay, at days 28 and 56, the SV-AS03 group showed significantly higher GMT titers compared to SV-PBS ( $p = 0.015$  and  $p < 0.001$ , respectively). All subjects within the SV-AS03 group showed seroconversion and seroprotection at day 56, contrasting to the 3 subjects in the SV-PBS group. As the vaccines used in this study were identical in composition to those used in previous studies, these results were anticipated. Overall, this indicates that the SV-AS03 vaccine is eliciting protective immune responses, while the SV-PBS vaccine failed to produce a significant response.

**Figure 3.2 AS03-adjuvanted H5N1 vaccination induced a protective immune response relative to non-adjuvanted vaccine.** (A) HAI and Nt antibody GMT and 95% CI at each time point by vaccine group; p-values are based on two-sided t-test on the log scale adjusting for unequal variances if necessary. No multiple testing adjustment was carried out. (B) HAI and Nt titers in individual subjects at days 28 and 56 by vaccine group; titer is represented by bar height (left y-axis) while fold change from baseline is shown as a connected black line (right y-axis), cut-offs are indicated by grey lines (solid: 1:40 titer, dashed: 4-fold change).<sup>30</sup>

### iTRAQ experiments

In order to identify the molecular mechanisms responsible for the differences seen in antibody responses between the SV-AS03 and SV-PBS vaccine groups, quantitative proteomic analysis was performed. An average of 2,900 proteins from 450 protein groups were identified in each 8-plex iTRAQ experiment. While identified proteins in each cell type did not largely differ in physical

properties (Figure 3.3), the number of identified proteins was higher in monocytes compared to the other immune cell types. This is consistent with previous reports suggesting that monocytes play an important role in responding to AS03.<sup>15, 18</sup>

**Figure 3.3 Experimental summary statistics by cell type.** \*: restricted to the representative protein in a protein group for which at least one of the 7 iTRAQ channels was quantified. Cell types across the bottom: B cells, Monocytes, Neutrophils, NK cells, T cells.

Using the top hit per protein group, the main analysis set was comprised of quantifications for 3,247 proteins (1,580 protein families based on 50% sequence identity) compared to the immune cell common standard. Broken down by cell type, 533 (T cells), 665 (NK cells), 813 (B cells), 860 (neutrophils), and 1,252 (monocytes) protein families were identified. Many proteins were only quantifiable in a subset of samples and we observed different levels of quantification sensitivity for the five cell types (Figure 3.4). For example, while 17.1% and 10.4% of monocyte and neutrophil proteins were quantified in at least 90% (126 out of 140) of their respective samples, the percentage ranged from 1.1-2.5% for the other cell types, indicating lower proteome coverage for those cell types (Figure 3.4). This could be due to the prevalence of highly abundant proteins diluting the low abundant signals, variability between subjects, different proteins being identified at different time points, or the common phenomenon of missing peptides in iTRAQ experiments.<sup>38-</sup>  
<sup>39</sup> Additionally, pooling the identified proteins from all cell types and time points showed higher levels of missing samples, indicating that disparate protein sets were identified across cell types. This is generally expected as the five immune cell types have different functions and timelines in the immune response.

**Figure 3.4 Empirical cumulative distribution function plots of protein missingness across samples.** Table on bottom indicates the number of samples that could be missing corresponding to the percentages.

### Multiple baseline time points enhance sensitivity

Vaccine studies traditionally use only one collected sample prior to vaccination as the baseline measurement. While this reduces sample numbers and costs to both researchers and volunteers, this practice may be allowing more inconsistency into the study because of the inherent variability of human biology. Variation in the three pre-vaccination time points was largely due to the immune cell type, similar to the variation in all time points (Figure 3.5).

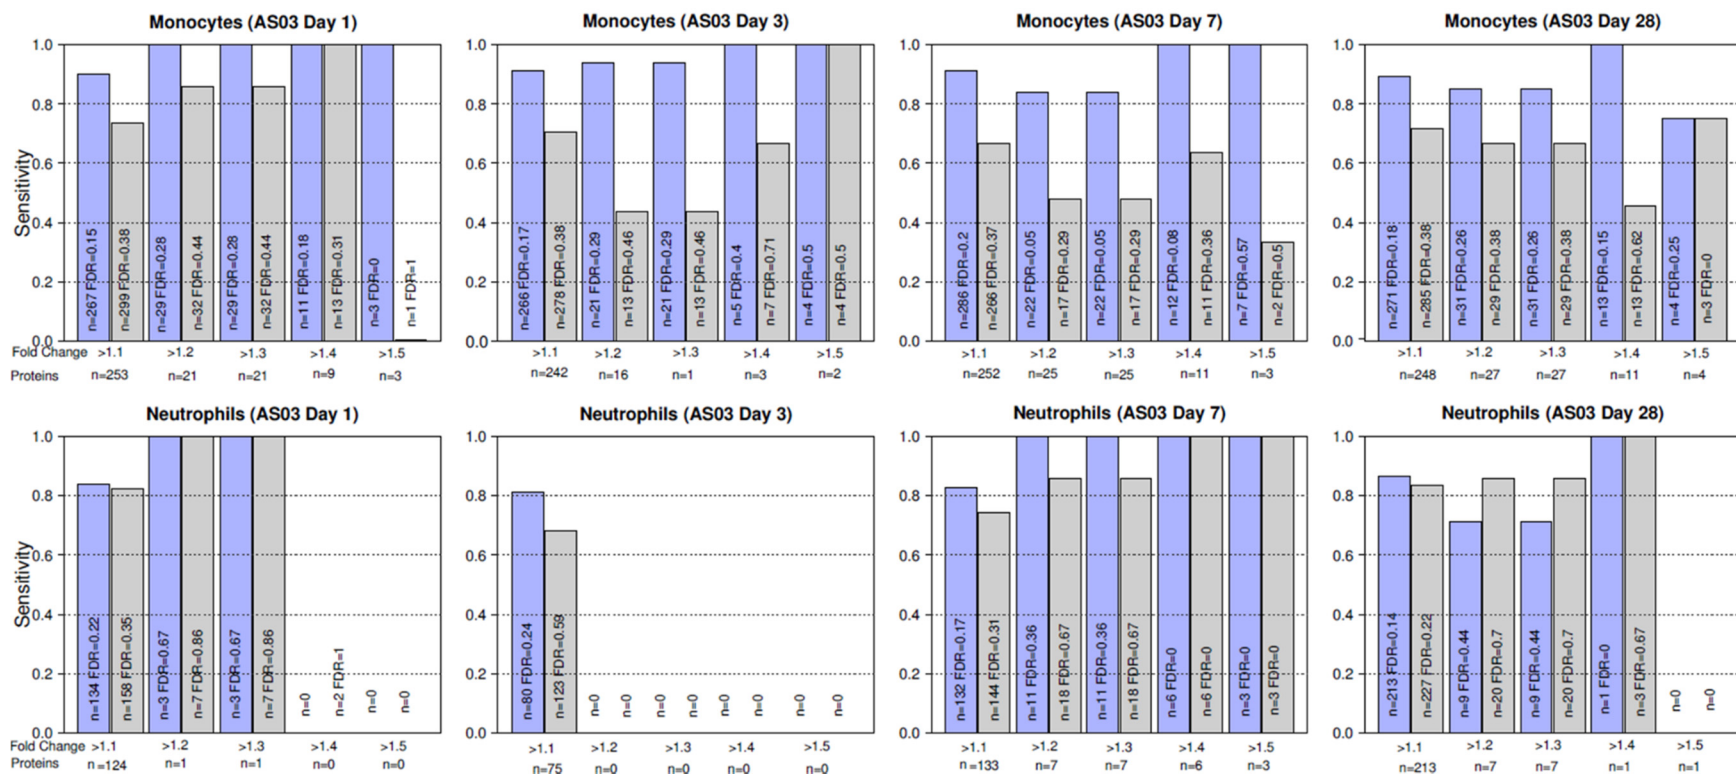

**Figure 3.5 Baseline variability shown by PCA biplots.** Variation at (A) pre-vaccination time points and (B) all time points is driven by cell type.

To assess the impact of using multiple baseline time points on the number of proteins identified, the results from all three baseline measures (day -28, -14, and 0) were compared to one (day 0), and two (day -14 and day 0) baseline measures for monocytes and neutrophils, as these cell types had the most proteins identified. With each additional baseline measurement included, the sensitivity of the protein identifications increased, as shown by the height of the bars (Figure 3.6). In almost all cases, including two baseline measures had at least 80% protein identification overlap with the three baseline measure dataset. Additionally, including more baseline measures

reduces the number of false positives in the data sets as the FDR is consistently higher when fewer baseline measurements are used (Figure 3.6). Monocytes at day 3 is the most striking example of the loss in sensitivity that occurs when fewer baseline measurements are collected. With fold change of  $>1.2$ , which this study used as a threshold, the sensitivity decreased from approximately 0.95 down to 0.45 when the number of baseline measures was reduced from two to one. Overall, the difference in sensitivity between using three and two baseline measures is relatively small. While increasing the number of baseline measurements also increases both the time and money costs for these studies, it gives more confidence in the results as well as potentially more identified proteins. Here, all three baseline measurements were averaged and used for the remaining analysis.

**Figure 3.6 Effect of multiple baseline timepoints.** Protein identification sensitivity for experiments using one (grey) or two (blue) baseline measures were compared to using all three for multiple fold change cutoffs. The FDR was also calculated for each case and is shown inside the bars. Different possible fold change cutoffs are across the bottom. The number of proteins identified at each fold change cutoff is shown by the n value either below the plots (three baseline time points) or inside the bars (one and two baseline time points)

### *AS03-modulated protein responses across time*

To compare the protein log<sub>2</sub> fold changes from baseline between the SV-AS03 and control SV-PBS vaccine groups, significant DA proteins were determined using a per-protein permutation test ( $p \leq 0.05$ ) and treatment fold change cutoff of  $\geq 1.2$  fold for each cell type at days 1, 3, 7, and 28 post-vaccination. The number of DA proteins (protein families) identified between the two vaccine groups for each cell type was: T cells: 60 (28); NK cells: 80 (40); B cells: 109 (50); neutrophils: 100 (55); and monocytes: 172 (108) (Table B-1 – Table B-20). Little overlap of DA proteins between post-vaccination time points within the same cell type was observed (Figure 3.7).<sup>29</sup> Lee *et al.* showed a similar transient response in mice infected with *Brucella abortus*.<sup>40</sup> They observed more proteins at the individual time points rather than shared between time points, which supports our hypothesis that different subsets of proteins are being activated at different times and that our selected time points were too far apart to show the overlap.

Of the 188 unique DA protein families, 64 (34%) were reported for at least two cell types, with TUBB3 (tubulin, beta 3 class III) family-related proteins being differentially abundant in all five cell types (Table B-21). Additionally, proteins in the HLA (major histocompatibility complex, class I) family were significantly differentially abundant in all cell types, except T cells and pyruvate kinase members were found for all immune cells except NK cells.

**Figure 3.7 Venn diagrams of differentially abundant proteins by cell type**

Overall, the observed vaccine effect between the SV-AS03 and SV-PBS groups was strongest for monocytes at day 1 and 3, both in terms of number (24 and 33) and percentage of protein families (77%) with higher responses in the SV-AS03 group (Figure 3.8). Additionally, differential protein responses in B cells at days 1 and 3 were primarily increased for the SV-AS03 group, which is likely associated with the B cells acting in their role as antigen presenting cells, as these time points are too early for the B cell antibody production. Finally, at day 1, neutrophils had a higher fraction of protein families that were elevated from baseline for the SV-AS03 group. The prevalence of increased proteomic responses in the SV-AS03 group for these time points suggests that AS03 induces early responses rather than bolstering the later responses.

Homologous proteins including many HLA-protein family members tended to cluster within their cell type based on their baseline fold changes (Figure 3.8). One exception was observed in NK cells at day 3, where HLA proteins clustered separately. Baseline response time trends for DA proteins from the HLA protein family showed that the mean response was higher in the SV-AS03 compared to the SV-PBS vaccine group in monocytes, neutrophils, and B cells (Figure 3.9). For all three cell types, an initial peak response was observed at day 3 for the SV-AS03 group with responses returning to near-baseline levels by day 7. In contrast to the other two cell types, neutrophils showed an additional increase in response for the SV-AS03 group at day 28, however there was an increase in unidentified proteins for a number of subjects at that time point. For NK cells, while HLA DA proteins showed consistent baseline trends with a peak at day 3, responses in the SV-PBS group were much more divergent with an overall higher mean response at day 1 compared to the SV-AS03 group, which could potentially be due to noise in those signals. Interestingly, there is an increase in HLA protein expression in the SV-PBS group from B cells, indicating that the unadjuvanted vaccine may be inducing HLA proteins in B cells only. This could be a possible mechanism for how a few of the subjects in the SV-PBS group showed seroconversion in their Nt titers, however this would need to be validated.

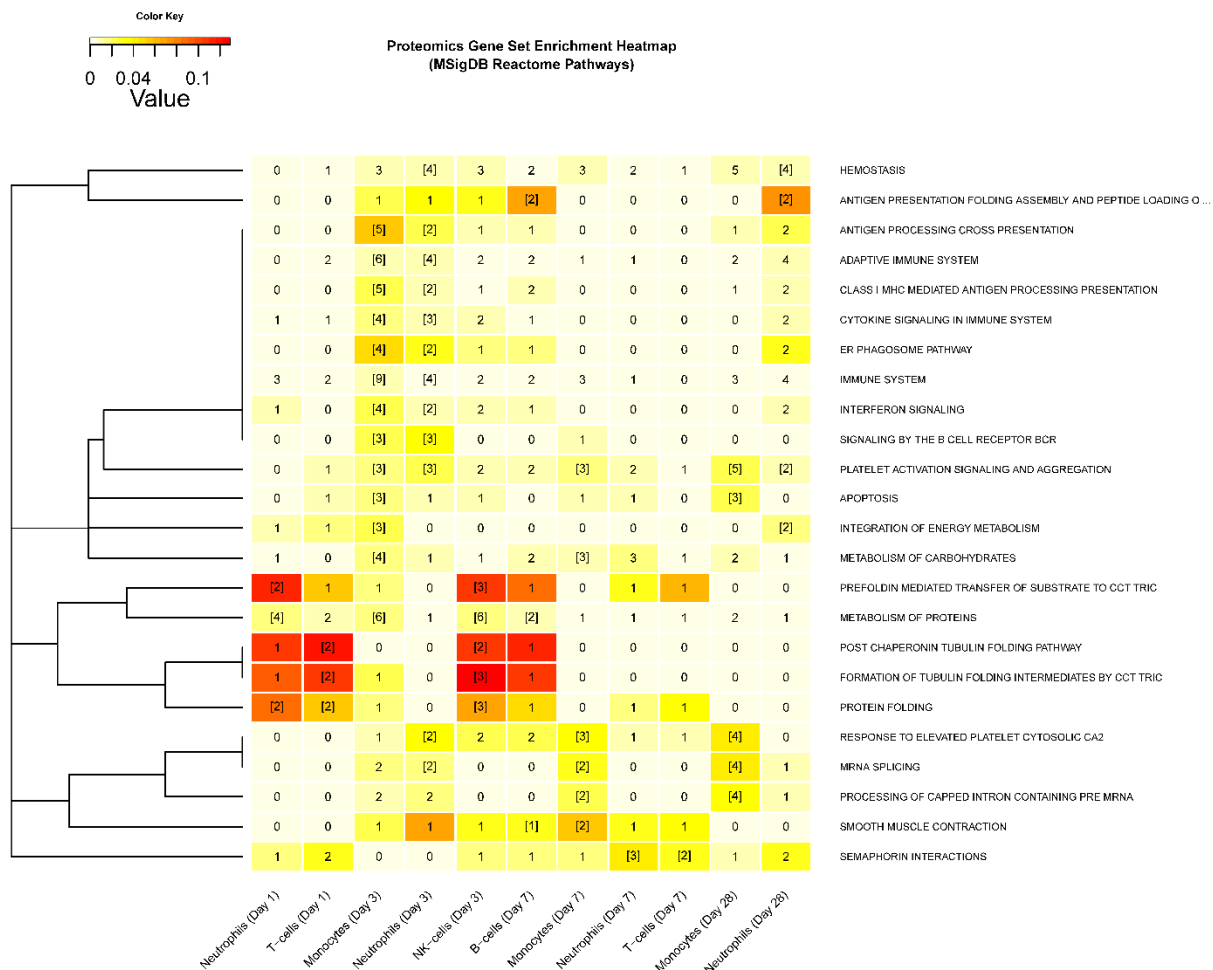

**Figure 3.8 Heatmaps of DA protein baseline  $\log_2$  fold changes for each cell type at each post-vaccination time point.** Dendrograms were obtained using complete linkage clustering of uncentered pairwise Pearson correlation distances between  $\log_2$  fold changes.  $\log_2$  fold changes of 0 were imputed for missing values. Protein cluster membership (50% sequence identity) is along the protein dendrogram on the left side; vaccine group membership is highlighted below the subject dendrogram at the top. Red: up-regulated from baseline; green: down-regulated from baseline; grey: missing observations. Larger versions of these heatmaps available in Appendix B

**Figure 3.9 HLA Class I family time trends of mean log<sub>2</sub> fold changes from baseline by vaccine group.** Data only includes cell types with differentially abundant HLA proteins. Individual HLA family protein time trends are plotted in lighter colors. The mean log<sub>2</sub> fold changes across all HLA protein family members are in bold.

### *AS03-induces antigen processing and presentation pathways*

Gene set enrichment analysis showed that genes encoding for DA proteins are involved in a range of biological processes including protein metabolism, tubulin folding, platelet activation, and immune system-related processes (Table B-22 -Table B-33). Antigen processing and presentation-related pathways were enriched in monocytes and neutrophils at day 3, including *Class I MHC-mediated antigen processing and presentation*, *Antigen processing and cross presentation*, and *ER phagosome* pathways (source: Reactome, Figure 3.10). This strongly suggests that SV-AS03 enhances antigen presentation at early time points, which is essential for the ultimate production of antibodies and activation of cytotoxic T-cells. Unexpectedly, *Antigen presentation folding assembly and peptide loading of class I MHC* was enriched for B cells at day 7, with the proteins being upregulated in the SV-AS03 group. While B cells are a professional APC, they usually present antigen to helper T cells via the MHC class II complex.<sup>41</sup> However, Hon *et al.* and others have shown that B cells are able to also participate in cross-presentation to present antigen to cytotoxic T cells via the MHC class I complex, which could be happening here.<sup>41-42</sup>

**Figure 3.10 Heatmap of enriched MSigDB Reactome pathways.** Gene sets significantly enriched in at least two conditions (cell type/time point combinations) are shown. Cells are color-coded by the Jaccard similarity index. Numbers in the cells represent the DA protein families in a set. Cells with protein family numbers in brackets indicate significantly enriched sets. Sets were clustered on the Jaccard distance between their binary enrichment pattern.

### *Antigen presentation and oxidative stress response proteins predict seroprotection status*

To identify AS03-modulated protein families that are predictive of seroprotection status (HAI titer  $\geq 1:40$ ) at day 56, regularized logistic regression analysis was performed using imputed protein family baseline responses as predictors (Table B-34 - Table B-37). To reduce the impact of missing observations on the imputation process, the analysis was performed on the most complete datasets (monocytes and neutrophils) and proteins with quantifications for 9 of 10 subjects in each vaccine group. MPO (myeloperoxidase) and SOD2 (superoxide dismutase 2) protein families, which are involved in inflammation and oxidative stress responses, were among

those identified as positive predictors of seroprotection in monocytes at day 1 (Table B-34). Surprisingly, while similar inflammation and oxidative stress-related protein families, including NCF4 (neutrophil cytosolic factor 4) and GZMB (granzyme B), were identified as predictors in neutrophils at day 1, they were negative predictors (Table B-37). In fact, the majority of the proteins included in the day 1 neutrophil model for seroprotection prediction were negative predictors, indicating that early time point neutrophils were potentially reducing the antibody response. Yang *et al.* previously reported that depletion of neutrophils following an adjuvanted vaccination actually increase the CD4+ T cell and antibody responses in mice.<sup>43</sup> While they were using neither AS03 nor H5N1 in their vaccinations, this could explain the negative association observed in the neutrophils.

Four of the 12 selected protein families identified as predictors of seroprotection in monocytes at day 3 were related to *Class I MHC-mediated antigen processing and presentation* including HLA (major histocompatibility complex, class I family), PSME 1 and PSME 2 (PA28 alpha/beta proteasome activator subunit families), as well as ITGB5 (integrin, beta 5 family) (Table B-35). For all these protein families, an increase in fold change from baseline resulted in an increased likelihood of seroprotection. Changes in PSME2 had the highest impact. The monocyte day 3 protein-protein interaction network (Figure 3.11) shows HLA and proteasome family proteins separated by two intermediate nodes indicating their close functional relationship. However, it remains unclear by what mechanism up-regulation of HLA class I molecules, proteasome activators, and other inflammation proteins enhance seroprotection.

### *Comparison of proteomic and transcriptomic data*

Differentially expressed (DE) genes (SV-AS03 vs. SV-PBS) identified in the transcriptomics study conducted in parallel<sup>30</sup> were compared to the proteomics results. Twenty-three DA protein families were associated with DE genes identified for any cell type-time point combination (Table 3.3). Interestingly, increased PSME1 and PSME2 proteomic responses for the SV-AS03 group in

**Figure 3.11 Monocyte day 3 protein-protein interaction network.** Human-human and human-*Influenza A* experimental interactions for which at least one interacting partner was differentially abundant between vaccine groups are shown. The mean log<sub>2</sub> fold change between vaccine groups was used if multiple Ensembl protein IDs mapped to one UniProt ID.

monocytes at day 3 corresponded with increased transcriptomic changes in the genes encoding these proteins in monocytes at day 1. Change in PSME2 were significant in both the proteomic and transcriptomic studies. While HLA Class I protein encoding genes were slightly up-regulated but not significantly differentially expressed in the SV-AS03 group in monocytes, the *Class I MHC-mediated antigen processing and presentation* pathway was significantly enriched in DE genes

up-regulated in SV-AS03 group at day 1.<sup>30</sup> Together these findings imply a delayed Class I-related antigen presentation response on the protein level (day 3) following an initial transcriptomics response at 24h post-vaccination. A post-transcriptional regulation mechanism may be modulating the expression of antigen processing and presentation proteins in monocytes.<sup>44</sup>

As anticipated, very few of the differential protein families (12%, 23 of 188) were identified in the transcriptomics analysis for any cell type-time point combination. This lack of shared responses has been seen in previous comparison studies<sup>45-46</sup> and likely stems from translational control of gene expression, degradation of mRNA prior to translation, post-translational modifications of proteins, bias towards highly abundant proteins, small sample size, and general noise in the data.<sup>47</sup> Despite the lack of individual shared responses, the proteomic analysis on the pathway level confirmed the enrichment of the *Class I antigen processing and presentation* pathway at day 1 based on transcriptomics results for monocytes and neutrophils albeit two days later (day 3, Figure 3.10).

## Conclusion

The goal of this study was to investigate the changes in immune cell proteomes after H5N1 vaccination with or without AS03 in order to better understand the mechanisms by which AS03 enhances protection. Even with a small sample size, this study highlights the strengths of assessing proteomic responses of multiple individual immune cell types in parallel by demonstrating a transient response to the AS03-adjuvanted influenza vaccine shown by modifications of the immune cell's proteomic profiles across the entire immune response. Furthermore, this study identified a strong antigen processing and presentation response at early time points that could also predict later seroprotection. In summary, the application of a cell-based proteomics approach allows a more granular assessment of immune cell-specific responses that, compared with transcriptomics results, revealed additional aspects of the immune responses to AS03-adjuvanted influenza vaccine.

**Table 3.3 Proteins encoded by genes determined to be differentially expressed in a parallel RNA-Seq experiment.** Protein families that contained at least one differentially abundant protein and at least one protein that was encoded by a differentially expressed gene were included.

## CHAPTER IV

### CONCLUSIONS AND PERSPECTIVES

#### Summary

Vaccines have significantly reduced world-wide mortality caused by infectious diseases by producing long-term immunological memory.<sup>1</sup> As a result, vaccines have been one of the most cost-effective advancements in medicine, particularly with influenza. Seasonal influenza outbreaks cause 3-5 million infections worldwide and the associated vaccines are typically 70-80% effective.<sup>2-3</sup> However, pandemic influenza vaccines, particularly avian influenzas, tend to not be particularly effective for unknown reasons.<sup>3</sup> Therefore, vaccine manufacturers have started using adjuvants to enhance the protective response from the vaccine and to help reduce the amount of antigen required.<sup>4</sup> While this approach has worked with moderate success for such adjuvants like monophosphoryl lipid A in the HPV vaccine and MF59 in one seasonal influenza vaccine,<sup>5</sup> the adjuvant AS03 has shown slower success due to initial safety issues.<sup>6-7</sup> By being associated with an increased risk of narcolepsy in children, even when more recent reports have implicated other causes,<sup>8-10</sup> AS03 has yet to be approved for the general public.

Studies examining how AS03 and its components work have largely been conducted using animal models.<sup>11-12</sup> However, they are not necessarily a good analogy for human studies.<sup>13-15</sup> Therefore, we sought to investigate the molecular mechanisms of AS03 on a cell-population level using a human cohort. First, cell purification and protein quantitation multiplexing strategies needed for a large study were developed, as described in Chapter II. Using both MACS and FACS, highly purified immune cell populations were collected for proteomics analysis, along with the standard PBMC fraction for comparison. By comparing two competing iTRAQ multiplexing strategies, it was shown that pooling together the same cell types at different time points was superior to pooling different cell types at the same time point, in terms of identifying cell-type

specific protein responses. Further, the fraction of shared differentially expressed proteins from each immune cell population with the unpurified immune cells was very small, indicating a more complete data set was obtained from the purified cells.

Chapter II introduced one of the first examples of using quantitative shotgun proteomic analysis in a systems vaccinology study. The majority of systems vaccinology reviews have discussed the benefit of including proteomics data, but fail to provide any such example.<sup>16-18</sup> Instead, they describe numerous studies utilizing transcriptomics and antibody responses.<sup>19-24</sup> Genomics, transcriptomics, and proteomics complement each other.<sup>25</sup> While the genome is static, transcriptomics and proteomics dynamically respond to environmental changes. Even so, the correlation between transcriptomics and proteomics can be low due to post-transcriptional regulatory mechanisms.<sup>26</sup> By including proteomics data, we can obtain a more comprehensive picture of the immune response following vaccination.

Building on the methods developed in Chapter II, Chapter III reported the results from a Phase I prospective clinical trial assessing the molecular immune responses of an H5N1 vaccine given with or without AS03 adjuvant. This trial represents the first instance of AS03 being investigated in humans by systems biology methods. Distinct responses were observed in all cell types, but monocytes demonstrated the strongest differential signal, followed by neutrophils. Antigen processing and presentation pathways were shown to be enriched in these cell types at early time points for both proteomic and transcriptomic analysis. Prediction models identified inflammation and oxidative stress proteins at day 1, as well as immunoproteasome subunits at day 3, as predictors of later seroprotective antibody responses. However, the correlation of these proteins to seroprotective antibody responses needs to be validated in a larger study. Once confirmed, this set of proteins could potentially be used to assess the effectiveness of the AS03-H5N1 vaccine. This would be especially important during a pandemic outbreak to determine if a person would ultimately achieve protection or if the dose would be better going to someone else.

## Study Limitations

Although the research described here identified many proteome changes in the immune response to influenza vaccines, some limitations were unavoidable. First, the small sample size of 2 subjects in Chapter II and 10 subjects per group in Chapter III limits the generalizability of our results. However, these studies demonstrate the strengths of analyzing proteomic responses in systems vaccinology studies. By including proteomics, additional aspects of the immune response were identified as compared to transcriptomics and serological analysis conducted alone, allowing for a more comprehensive picture of the immune response. Second, since this pilot study and clinical trial was conceptualized, designed, and conducted, new mass spectrometry methods using MS3<sup>27</sup> and MultiNotch MS3<sup>28</sup> for iTRAQ analysis have been published. These methods show a reduction in the ratio distortion seen in iTRAQ experiments and allow for more proteins to be quantified overall. While we were unable to adopt the newer methods in these studies, due to the limitations on altering protocols after they are approved and the trial begins, future systems vaccinology studies will greatly benefit from these enhancements. This, however, does not discredit the observations made here; it just suggests that additional information could have been obtained. Finally, the immune cells used in these studies were purified from venous whole blood, rather than a combination of venous blood, lymphoid tissues, and muscle tissue at the site of injection. After APCs come in contact with a pathogen, they migrate to the lymph nodes in order to activate the adaptive immune response.<sup>29</sup> By sampling only blood, “fresh” immune cells are likely being sampled more than any activated ones over time, leading to important signals being diluted. Blood is a relatively quick and easy sample to collect and it was not possible to collect lymphoid and muscle tissue from healthy human subjects. Even with using only blood, models of protein combinations that could predict later seroprotection status were identified. It is reasonable to hypothesize that these models, based on blood, may be useful in the case of a H5N1 pandemic outbreak in order to quickly identify those who will achieve protection from the vaccine.

## Future Directions

### *Protein Validation Studies*

The clinical trial described in Chapter III identified hundreds of proteins that were differentially expressed between subjects who received AS03-H5N1 and those who received the control PBS-H5N1 vaccine. A small subset of these proteins were further selected in prediction models for seroprotection. However, in order for these proteins and models to be fully applied as correlates of protection, they must be validated and confirmed. The Link lab is currently working on methods to validate both the proteomics and transcriptomics results using a human monocyte THP-1 cell line.

Western blotting has historically been considered the gold standard for validating protein quantitation, however the field is moving more toward multiple reaction monitoring (MRM) for validation, as it is more reliable, reproducible, and accurate.<sup>30</sup> MRM is a targeted mass spectrometry approach that measures only the precursor and fragment ions of analytes of interest as transitions.<sup>31</sup> During MRM method development, a list of proteins of interest are imported into Skyline,<sup>32</sup> where the program fragments the proteins *in silico* and provides lists of possible transitions based on spectral libraries. This list is then narrowed down to pick at least three proteotypic peptides per protein and at least three transitions per peptide for scouting runs. Scouting runs test the detectability, stability, and reproducibility of the transitions. The MRM transition list is then reduced further iteratively until a final method is produced. Finally, synthetic peptides corresponding to the proteins of interest are used as internal standards to obtain the quantitative information. Currently, the initial transition list for the scouting runs has been made for validation of the monocyte data. However, there are a number of steps to be completed before the method will be usable for the validation of the clinical trial proteins. Further, this process will need to be completed for the neutrophil results, if not all the remaining cell types.

### *Metabolomics*

Metabolomics is considered the “final frontier” in systems biology.<sup>17, 33</sup> Therefore, investigating the metabolomic response to an AS03-adjuvanted H5N1 vaccine is a logical step for further understanding how it works. Metabolomics is the method of measuring and identifying small molecules, typically under 2000 Da. As the components of AS03 are all small molecules, it is possible to hypothesize that the degradation products could be measured throughout the immune response allowing for a better understanding of both the immune response and the pharmacokinetics of the adjuvant. Million Tegenge and Robert Mitkus created a physiologically based pharmacokinetic model which predicted that  $\alpha$ -tocopherol would peak in serum at 8 hours, rapidly transfer to draining lymph nodes, and be stored in adipose tissue.<sup>34</sup> However, their model was based on data collected from studies conducted in sheep and required a number of informed assumptions regarding human biology. By using metabolomics, the components of AS03 could be followed after vaccination to fully understand how they work, rather than relying on assumptions.

Further, the AS03-adjuvant degradation products could also be stimulating the immune response themselves, as metabolites can regulate signal transduction and regulate immune functions.<sup>17, 35</sup> The application of metabolomics to studying vaccines is relatively new, however one study identified sets of metabolites that differentiated between vaccinated and unvaccinated cows.<sup>36</sup> Similar to our proteomics analysis, the metabolites identified would also need to be validated.

### *AS03 Mechanism of Action*

Understanding the exact mechanism of how AS03 works is vitally important for it to be licensed for general use. The best way to investigate this would be to compare the response of AS03 alone to the response of the AS03-H5N1 vaccine and the response of an unadjuvanted H5N1 vaccine. This three-way comparison would help identify which signals stem from AS03, rather than the

normal response to an antigen. Ethical concerns prohibit the use of AS03 alone without a vaccine in humans, as it has not been assessed for safety in that manner. Therefore, these experiment will have be carried out in cell culture and animal models. While the methods outlined in Chapters II-III can and should be applied to these experiments, the data obtained will not be fully comparable to the human results.

In order to get the most complete understanding of the AS03 mechanism of action, all of the omics data from the human clinical trial and any cell culture/animal model experiments would need to be compared and integrated. This is the area where systems vaccinology faces the most challenges ahead. Individual omics studies generate enormous amounts of data and systems vaccinology aims to integrate many different types of omics studies (Figure 4.1). Effectively combining multiple omics datasets requires understanding each one individually statistically and biologically, as they all come with their own background and experimental noise, complexity, and format.<sup>37-38</sup> While there are tools to aid in the integration of multiple data types, they mainly are derived from methods for analyzing one data type and therefore do not completely bridge the gap.<sup>38</sup> Furthermore, these methods are mathematically complex to both operate and understand. Until a tool that will effectively combine all omics data types is developed, it will be difficult to produce a complete mechanism of action for AS03 or any other adjuvant.

**Figure 4.1 Overview of systems vaccinology methods.** Systems vaccinology aims to collect and integrate data from all components of the immune response. A combination of standardized immune serologic assays with the high-throughput transcriptomic, proteomic, and metabolomic measurements will provide the opportunity to predict immunologic protection from vaccines.<sup>17</sup> Reprinted from Seminars in Immunology, with permission from Elsevier.

## Conclusion

Applying quantitative proteomics to the field of systems vaccinology represents a step forward for understanding the immune response to vaccines on a granular level. Overall, the methods in this dissertation outline the benefit of both separating the individual immune cell populations and using quantitative proteomics to study the immune response to vaccines. Many differences were observed when the responses from purified individual immune cell types were compared to PBMC after a seasonal influenza vaccine. Each individual immune cell type showed unique biological networks associated with their differential proteins. Further, when the developed methods were applied during a clinical trial of an AS03-adjuvanted H5N1 vaccine, monocytes and neutrophils showed significant upregulation of antigen processing and presentation proteins, which corresponded to similar results observed at the transcriptomics level. The approaches outlined here can guide future systems biology studies aimed at modeling and predicting complex responses to vaccines, vaccine adjuvants, or even natural infections between multiple cell types.

### SUPPORTING INFORMATION: CHAPTER II

The following three tables are too large to be included in this document, but can be accessed from the provided links. Each file reports normalized pseudospectral counts (NPSC) that were calculated in *ProteoIQ*. A value of zero indicates a protein was identified but not quantified, while an NA value indicates a protein was not identified in that sample at all.

**Table A-1 Normalized protein expression in human immune cells prior to and post-TIV vaccination.**

**Table A-4 Top networks and pathways identified in TIV-vaccinated subjects**

	Top Network Description	Top Canonical Pathway
<b>d0-1</b>		
<b>PBMC</b>	Hematological disease, reproductive system development and function, cellular assembly and organization	Granzyme A signaling
<b>T cell</b>	Endocrine system development and function, molecular transport, small molecule biochemistry	Mechanisms of viral exit from host cells
<b>B cell</b>	Cellular assembly and organization, cellular function and maintenance, nervous system development and function	Pyruvate fermentation to lactate
<b>NK</b>	Cellular assembly and organization, DNA replication, recombination and repair, post-translational modification	Granzyme A signaling
<b>Monocyte</b>	Dermatological disease and conditions, antimicrobial response, inflammatory response	Methylglyoxal degradation III
<b>Neutrophil</b>	Hematological system development and function, tissue morphology, cellular development	RhoGDI signaling
<b>d0-3</b>		
<b>PBMC</b>	Cellular assembly and organization, DNA replication, recombination and repair, connective tissue development and function	Granzyme A signaling
<b>T cell</b>	Hereditary disorder, metabolic disease, neurological disorder	Inhibition of angiogenesis by TSP1
<b>B cell</b>	Protein synthesis, RNA post-transcriptional modification, molecular transport	Lipid antigen presentation by CD1
<b>NK</b>	Cellular movement, hematological system development and function, immune cell trafficking	Actin cytoskeleton signaling
<b>Monocyte</b>	Cancer, endocrine system disorders, hematological disease	Sertoli cell-sertoli cell junction signaling
<b>Neutrophil</b>	Cell morphology, hereditary disorder, nervous system development and function	Pentose phosphate pathway (non-oxidative)
<b>d0-7</b>		
<b>PBMC</b>	Cellular assembly and organization, DNA replication, recombination and repair, cell cycle	Granzyme A signaling
<b>T cell</b>	Cell death and survival, embryonic development, post translational modification	Oxidative phosphorylation
<b>B cell</b>	Nucleic acid metabolism, cardiac arrhythmia, cardiovascular disease	Mitochondrial dysfunction
<b>NK</b>	Free radical scavenging, molecular transport, cellular assembly and organization	Regulation of actin-based motility by Rho
<b>Monocyte</b>	Cell death and survival, cellular compromise, protein trafficking	Neuroprotective role of THOP1 in Alzheimer's disease
<b>Neutrophil</b>	Cellular assembly and organization, cellular function and maintenance, neurological disease	Amyotrophic lateral sclerosis signaling

## APPENDIX B

### SUPPORTING INFORMATION: CHAPTER III

#### **Supplemental Methods**

##### *Ethics statement*

This study was approved by the Vanderbilt University Institutional Review Board, and the study was conducted in accordance with Good Clinical Practice, the Declaration of Helsinki, the US Code of Federal Regulations for the Protection of Human Subjects, and the Department of Health and Human Services Belmont Report. The study is registered on ClinicalTrials.gov (No. NCT01573312). All subjects provided written informed consent prior to initiation of study procedures. Subjects were assigned de-identified code numbers and their privacy strictly held in trust by study personnel, sponsors, and their agents. This confidentiality extends to cover testing of biological samples, in addition to the clinical information related to participants.

##### *Study products*

Inactivated monovalent influenza A/Indonesia/05/2005 H5N1 split-virus vaccine at a dosage of 3.75 mcg and phosphate buffered saline (PBS) diluent were both manufactured by Sanofi Pasteur. The AS03 adjuvant was manufactured by GlaxoSmithKline (GSK) and contained 4.86 mg polysorbate 80, 11.86 mg  $\alpha$ -tocopherol, and 10.69 mg squalene in an oil-in-water emulsion. The vaccine and adjuvant were provided by the US Department of Health and Human Services Biomedical Advanced Research and Development Authority from the National Pre-pandemic Influenza Vaccine Stockpile.

### *Analysis population*

The systems biology analysis population included all subjects who met all inclusion and exclusion criteria, who contributed at least one pre-vaccination blood sample (at Day -28, -14, or 0) and at least one post-vaccination blood sample (at Day 1, 3, 7, or 28) for which valid results were reported. The analyses included subjects by study product actually received. This population included 20 subjects (10 for each treatment group) including a subject in the SV-AS03 vaccine group, who received the second vaccination (Day 28) out-of-window. Time points with outlying measurements were identified separately for each assay.

### *Reference Channel Selection*

In order to determine the most advantageous method for normalizing the data within ProteoIQ, randomly selected donors and cell type data were analyzed first using Day 0 as the reference channel and second with ICCS as the reference channel. The  $\log_2$  ratios were exported for each method and plotted against each other in R (Figure B-11A). While both methods showed moderate correlation for peptides quantitated in both experiments (Figure B-11B), the experiment using ICCS as the reference channel showed more quantitated peptides overall. Further, a Bland-Altman plot showing the agreement between the two methods (Figure B-11C) showed a slight bias towards higher quantitation values in the method using ICCS as the reference, however with a value of 0.03122, the bias was small enough to not be considered. Therefore, the remaining analyses were performed using ICCS selected as the reference channel.

### *Normalization*

To account for systematic differences in the protein ratio distributions between iTRAQ experiments for the same cell type, protein ratios were normalized within cell type on the  $\log_2$  scale to align the medians of the protein ratio distributions across cell type samples. The following steps were taken for each cell type:

- (1) For each sample (140 per cell type), the median of the protein ratio distribution was determined using the quantifications obtained from the reference (top) protein within a protein group
- (2) The median of all the sample medians calculated in (1) was obtained
- (3) A sample specific scaling factor was then calculated as the difference between the cell type-specific median obtained in (2) and the sample-specific median obtained in (1)
- (4) The protein ratio distribution for each sample was then normalized by adding the scaling factor determined in (3).

Subject specific  $\log_2$  protein fold changes from baseline were calculated for each subject and post-vaccination day by subtracting the mean of the normalized  $\log_2$  baseline ratios from each of the subject's post-vaccination day ratios.

## **Supplementary Results**

### *Quality Control*

Due to the large number of experiments, samples were checked for consistency at different times during analysis. After digestion, the number of peptides and proteins identified helped determine if there were losses during the desalting step by solid phase extraction or if the original quantitation of protein was incorrect (Figure B-9). After each iTRAQ experiment, the two yeast proteins were used to determine if there was inconsistency within the experiment (Figure B-10A,B), indicating errors in labeling efficiency. The yeast proteins were also used after all 20 experiments of the same cell type were run to determine if any experiments appeared as outliers (Figure B-10C,D).

Figure B-2 Boxplots of  $\log_2$  ICCS ratios before median normalization. Outliers are omitted for clarity.

**Figure B-3** Boxplots of  $\log_2$  ICCS ratios after median normalization. Median normalization within cell type aligned protein ratio distributions, while retaining cell-type median centers. Outliers are omitted for clarity.

**Figure B-4 Heatmaps of DA protein baseline log<sub>2</sub> fold changes for B cells at each post-vaccination time point.** Dendrograms were obtained using complete linkage clustering of uncentered pairwise Pearson correlation distances between log<sub>2</sub> fold changes. Llog<sub>2</sub> fold changes of 0 were imputed for missing values. Protein cluster membership (50% sequence identity) is along the protein dendrogram on the left side; vaccine group membership is highlighted below the subject dendrogram at the top. Red: up-regulated from baseline; green: down-regulated from baseline; grey: missing observations.

**Figure B-5 Heatmaps of DA protein baseline log<sub>2</sub> fold changes for monocytes at each post-vaccination time point.** Dendrograms were obtained using complete linkage clustering of uncentered pairwise Pearson correlation distances between log<sub>2</sub> fold changes. Log<sub>2</sub> fold changes of 0 were imputed for missing values. Protein cluster membership (50% sequence identity) is along the protein dendrogram on the left side; vaccine group membership is highlighted below the subject dendrogram at the top. Red: up-regulated from baseline; green: down-regulated from baseline; grey: missing observations

**Figure B-6 Heatmaps of DA protein baseline log<sub>2</sub> fold changes for neutrophils at each post-vaccination time point.** Dendrograms were obtained using complete linkage clustering of uncentered pairwise Pearson correlation distances between log<sub>2</sub> fold changes. Log<sub>2</sub> fold changes of 0 were imputed for missing values. Protein cluster membership (50% sequence identity) is along the protein dendrogram on the left side; vaccine group membership is highlighted below the subject dendrogram at the top. Red: up-regulated from baseline; green: down-regulated from baseline; grey: missing observations

**Figure B-7 Heatmaps of DA protein baseline  $\log_2$  fold changes for NK cells at each post-vaccination time point.** Dendrograms were obtained using complete linkage clustering of uncentered pairwise Pearson correlation distances between  $\log_2$  fold changes.  $\log_2$  fold changes of 0 were imputed for missing values. Protein cluster membership (50% sequence identity) is along the protein dendrogram on the left side; vaccine group membership is highlighted below the subject dendrogram at the top. Red: up-regulated from baseline; green: down-regulated from baseline; grey: missing observations

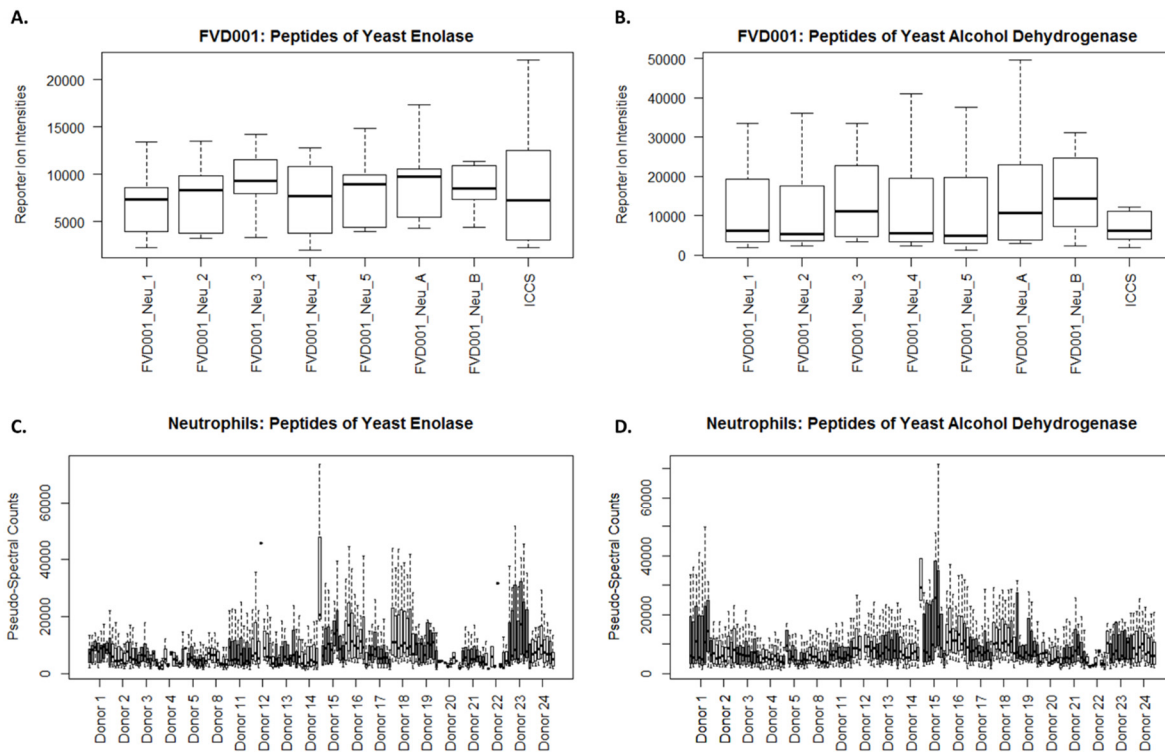

**Figure B-8 Heatmaps of DA protein baseline  $\log_2$  fold changes for T cells at each post-vaccination time point.** Dendrograms were obtained using complete linkage clustering of uncentered pairwise Pearson correlation distances between  $\log_2$  fold changes.  $\log_2$  fold changes of 0 were imputed for missing values. Protein cluster membership (50% sequence identity) is along the protein dendrogram on the left side; vaccine group membership is highlighted below the subject dendrogram at the top. Red: up-regulated from baseline; green: down-regulated from baseline; grey: missing observations

**Figure B-9 Neutrophil experiments control chart.** The number of proteins identified in each sample (from X!Tandem) were plotted over time. The middle bold dashed line indicates the average number of proteins identified across all neutrophil samples. The other lines indicate the 1<sup>st</sup> and 2<sup>nd</sup> standard deviation control limits in each direction

**Figure B-10 Boxplots assessing response of internal standard yeast proteins.** The reporter ion intensities of the individual peptides of (A) yeast enolase and (B) yeast alcohol dehydrogenase were plotted for each individual sample. Similarly, the pseudo-spectral counts on the protein level of (C) yeast enolase and (D) yeast alcohol dehydrogenase were compared to identify any inconsistent experiments or samples

**Figure B-11 Comparison of peptide normalization methods.** (A) Exported log<sub>2</sub> ratios from an experiment using Day 0 as reference versus ICCS as reference showing that there were more peptides quantified when ICCS was the reference. ProteoIQ uses values of -10 when quantifications cannot be made. (B) Zoomed in plot of the cluster from (A) with a linear regression showing the moderate correlation between the methods. (C) Bland-Altman plot assessing the agreement between the two methods. Each point represents a protein. The mean value (bias) was slightly increased from 0. The upper and lower limits were defined as the second standard deviations from the mean of the difference between methods.

**Table B-1 Differentially abundant proteins for B cells at Day 1.** Proteins with the same ICCS-ratio were grouped together and represented by the longest protein in the group. \*mean baseline log<sub>2</sub> fold change.

## APPENDIX C

### ASSESSMENT OF INSTRUMENT STABILITY

Due to requiring the LTQ mass spectrometer to run 700 samples for quality control, a stability test was performed to determine the stability of it and the Thermo PAL autosampler. Ten aliquots of Pepmix (Table C-1) were loaded into the autosampler and run in triplicate using a 60 min gradient (5-45% acetonitrile). The raw files were converted to mxzml format and analyzed using X!Tandem. The number of peptides identified and the glufib peak area were plotted to observe any trends between the samples (Figure C-1).

**Table C-1 Components of Pepmix Samples**

Concentration (fmol/ $\mu$ L)	Peptide/Protein Digest	Company
50	BSA Digest Standard	Protea
50	Yeast ( <i>S. cerevisiae</i> ) alcohol dehydrogenase	Protea
50	Yeast ( <i>S. cerevisiae</i> ) enolase	Protea
50	Glu-1-Fibrinopeptide B	Protea
100	Angiotensin II	Sigma Aldrich
100	ACTH	Sigma Aldrich

**Figure C-1 Assessment of stability in LTQ.** (A) Glufib peptide peak area and (B) number of peptides identified in triplicate experiments of 10 pepmix samples shows some variability across samples, but overall no significant differences between samples.

Glufib was chosen as the peptide to monitor for stability, as it is added to each sample prior to MS analysis to monitor the chromatography and instrument response. The peak area of glufib and the total number of peptides tracked similar patterns over the 10 pepmix samples. While there is variability across samples, there is no significant differences due to the overlap of the error bars. The high standard deviation was determined to be due to an issue in the autosampler picking up such a small volume (1  $\mu$ L). Overall, it was determined that the instrument and autosampler was stable enough to run the QC samples. Additional pepmix samples and blanks were run during QC experiments to ensure continued stability of the instrument.

## EDUCATION

---

**Vanderbilt University** Nashville, TN  
**Ph.D., Chemistry** May 2017  
Advisor: Dr. Andrew J. Link  
Dissertation Title: Quantitative Proteomic Analysis of the Human Immune Response following Influenza Vaccination

**Eastern Kentucky University** Richmond, KY  
**B.S., Forensic Science**, concentration in Forensic Chemistry May 2012  
**B.S., Chemistry**, ACS certified May 2012  
**Minor: Statistics** **GPA: 3.97**  
Honors Diploma and *Summa Cum Laude*

## RESEARCH EXPERIENCE

---

**Graduate Research Assistant** April 2013 - Present  
Vanderbilt University Nashville, TN

- Performed sample preparation and shotgun proteomic analysis of human immune cell subtypes to investigate the changes made in regards to adjuvanted and non-adjuvanted influenza vaccines
- Collaborated across many disciplines (immunologists, microbiologists, statisticians, clinicians)
- Analyzed large datasets using various proteomics and systems biology software programs
- Maintained and troubleshot mass spectrometers and HPLC pumps
- Performed gel electrophoresis, western blotting, and co-immunoprecipitation to purify proteins

**Research Assistant, Organic and Analytical Lab** Jan 2011 – May 2012  
Eastern Kentucky University Richmond, KY

- Conducted novel synthetic developments towards ergovaline
  - Optimized the condensation of proline and valine into their diketopiperazine product
- Characterized synthesized compounds using DART-MS

**Student Intern/ Laboratory Technician, Veterinary Diagnostic Lab** May 2011 – May 2012  
University of Kentucky Veterinary Diagnostic Laboratory Lexington, KY

- Examined ergovaline stability in fescue grass over time and at different temperatures
  - Aided in the determination of superior sample collection and storage methods for fescue samples
- Perform other diagnostic tests as needed using various types of instrumentation (nitrate/nitrite levels in ocular fluid using colorimetric techniques, heavy metal levels using ICP-MS)
